

# Exchange Competition, Entry, and Welfare\*

Giovanni Cespa<sup>†</sup> and Xavier Vives<sup>‡</sup>

December 2019

## Abstract

We assess the consequences for market quality and welfare of different entry regimes and exchange pricing policies, integrating a microstructure model with a free-entry, exchange competition model where exchanges have market power in technological services. We find that services can be strategic substitutes or complements. Free-entry delivers superior liquidity and welfare outcomes vis-à-vis an unregulated monopoly, but entry can be excessive or insufficient. Depending on the extent of the monopolist's technological services undersupply compared to the First Best, a planner can achieve a higher welfare controlling entry or platform fees.

*Keywords:* Market fragmentation, welfare, endogenous market structure, platform competition, Cournot with free entry, industrial organization of exchanges.

*JEL Classification Numbers:* G10, G12, G14

“We are now living in a much different world, where many are questioning whether the pendulum has swung too far and we have too many venues, creating unnecessary complexity and costs for investors.” Mary Jo White, Economic Club of New York, June 2014.

“The cost of market data and exchange access has been a cause of debate and concern for the industry for many years, and those concerns have grown as these costs have risen dramatically in the last several years [...] Exchanges also have been able to charge more for the data center connections [...] since they control access at the locations where the data is produced.” Brad Katsuyama, U.S. House of Representatives Committee on Financial Services, June 2017.

## 1 Introduction

Over the past two decades, governments and regulators moved to foster competition among trading venues, leading to an increase in market fragmentation. However, there is now a concern that the entry of new platforms may have been excessive, and that exchanges exercise too much market power in the provision of technological services. In this paper we show that the move from monopoly to competition has increased liquidity and the welfare of market participants but that the market does not deliver a (constrained) efficient outcome. We characterize how structural and conduct regulation of exchanges has the potential to improve welfare.

The profit orientation of exchanges, when they converted into publicly listed companies, led to regulatory intervention both in the US (Reg NMS in 2005) and the EU (Mifid in 2007), to stem their market power in setting fees. Regulation, together with the removal of barriers to international capital flows and technological developments, led in turn to an increase in fragmentation and competition among trading platforms. Incumbent exchanges such as the NYSE reacted to increased competition by upgrading technology (e.g, creating, NYSE Arca), or merging with other exchanges (e.g., the NYSE merged with Archipelago in 2005 and with Euronext in 2007).<sup>1</sup>

As a result, the trading landscape has changed dramatically. On the one hand, large-cap stocks nowadays commonly trade in multiple venues, a fact that has led to an inexorable decline in incumbents’ market shares, giving rise to a “cross-sectional”

---

<sup>1</sup>See Foucault et al. (2013), Chapter 1.

dimension of market fragmentation (see Figure 1). The automation of the trading process has also spurred fragmentation along a “time-series” dimension, in that some liquidity providers’ market participation is limited (Duffie (2010), SEC (2010)), endogenous (Anand and Venkataraman (2016)), or impaired because of the existence of limits to the access of reliable and timely market information (Ding et al. (2014)).<sup>2</sup> On the other hand, trading fees have declined to competitive levels (see, e.g., Foucault et al. (2013), Menkveld (2016), and Budish et al. (2019)), and exchanges have steered their business models towards the provision of technological services (e.g., proprietary data, and co-location space).<sup>3</sup>

Figure 1: Market shares among trading venues in Europe, 2018 (Panel (a)), and the US, 2018 (Panel (b)). Source: CBOE Global Markets, own calculations (See Table 1 for venues’ classification).

Such a paradigm shift has raised a number of concerns highlighted by the fact that even though there are 13 lit stock venues in the US (and 30 alternative ones), 12 of them, which account for two-thirds of daily trading, are controlled by three major

<sup>2</sup>Limited market participation of liquidity providers also arises because of shortages of arbitrage capital (Duffie (2010)) and/or traders’ inattention or monitoring costs (Abel et al. (2013)).

<sup>3</sup>Increasing competition in trading services has squeezed the profit margins exchanges drew from traditional activities, leading them to gear their business model towards the provision of technological services (Cantillon and Yin (2011)). There is abundant evidence testifying to such a paradigmatic shift. For example, according to the Financial Times, “After a company-wide review Ms Friedman [Nasdaq CEO] has determined the future lies in technology, data and analytics, which collectively accounted for about 35 per cent of net sales in the first half of this year.” (see, “Nasdaq’s future lies in tech, data and analytics, says Nasdaq CEO” *Financial Times*, October 2017). Additionally, according to Tabb Group, in the US, exchange data, access, and technology revenues have increased by approximately 62% from 2010 to 2015 (Tabb Group, 2016).

players: Intercontinental Exchange, Nasdaq, and CBOE.<sup>4</sup> Indeed, market participants allege that exchanges exercise market power in the provision of technological services.<sup>5</sup> Additionally, regulators and policy makers such as the SEC and the antitrust authorities have also expressed concern about the existence of potential monopoly restrictions or excess entry.<sup>6</sup>

What is the character of platform competition in the supply of technological services? What is the impact of platform competition on the overall quality of the market and on the end users of trading services? If the market outcome is suboptimal, which regulatory tools are more effective? Entry controls (merger policy), or fee regulation?

We assess the consequences for market quality and the welfare of market participants of different exchanges' entry regimes and pricing policies in a context of limited market participation. To this end we propose a stylized framework that captures the above dimensions of market fragmentation and competition among trading venues, integrating a simple two-period, market microstructure model à la Grossman and Miller (1988), with one of platform competition with entry, featuring a finite number of exchanges competing to attract dealers' orders.

The microstructure model defines the *liquidity determination* stage of the game. There, two classes of risk averse dealers provide liquidity to two cohorts of rational liquidity traders, who sequentially enter the market. Depending on the structure of the market, at each round traders can submit their orders only to an "established" venue,

---

<sup>4</sup>See FT January 8, 2019, where it is also reported that large brokers and banks are setting MEMX a competing exchange to lower costs of trading.

<sup>5</sup>"'Information wants to be free,' the technology activist Stewart Brand once said. 'Information also wants to be expensive.' That is proving true on Wall Street, where stock exchanges—in particular the New York Stock Exchange and Nasdaq—both publicly traded and for-profit, stand accused by rivals and some users of unfairly increasing the price of market data." (*Business Insider*, November 2016). In December 2016 Chicago-based Wolverine Trading LLC stated to the SEC that its total costs related to NYSE equities market data had more than tripled from 2008 to 2016 ("This is a monopoly.")

<sup>6</sup>Responding to a NYSE request to change the fees it charges for premium connectivity services, the SEC in November 2016 stated: "The Commission is concerned that the Exchange has not supported its argument that there are viable alternatives for Users inside the data center in lieu of obtaining such information from the Exchange. The Commission seeks comment on whether Users do have viable alternatives to paying the Exchange a connectivity fee for the NYSE Premium Data Products." The SEC statement echoes industry concerns "'We are pleased that the Commission will be subjecting this incremental fee application to review,' Doug Cifu, the CEO of electronic trading firm Virtu [...] 'As we have repeatedly said we think exchange market data and connectivity fees have 'jumped the shark' as an excessive cost burden on the industry.'" (*Business Insider*, November 2016.) In October 2018, the SEC did not approve the fee increase for data sought by the NYSE and Nasdaq. See also Okuliar (2014) on whether US competition authorities should intervene more in financial exchange consolidation.

or also to one of the competing venues. Dealers in the first class are endowed with a technology enabling them to act at both rounds, absorbing the orders of both liquidity traders' cohorts, and are therefore called 'full' (FD); those in the second class can only act in the first round, and are called 'standard' (SD). The possibility to trade in the two rounds captures in a simple way both the limited market participation of standard dealers, and FD's ability to take advantage of short term return predictability. We assume that there is a best price rule ensuring that the transaction price is identical across all the competing trading platforms. This is the case in the US where the combination of the Unlisted Trading Privilege (which allows a security listed on any exchange to be traded by other exchanges), and RegNMS's protection against "trade-throughs," implies that, despite fragmentation, there virtually exists a unique price for each security.<sup>7</sup> We also assume that trading fees are set at the competitive level by the exchanges.<sup>8</sup>

The platform competition model features a finite number of exchanges which, upon incurring a fixed entry cost, offer "technological services" to the full dealers that allow them to trade in the second round. A standard dealer becomes full by paying a fee reflecting the incremental payoff he earns by operating in the second round.<sup>9</sup> This defines an inverse demand for technological capacity. Upon entry, each exchange incurs a constant marginal cost to produce a unit of technological service capacity, receiving the corresponding fee from the attracted full dealers. This defines a Cournot game with free entry in which the *technological capacity* offered by exchanges is determined. Note that the Cournot specification of the platform game is appropriate since even if there is price competition after the capacity choice, the strategic variable is costly capacity.<sup>10</sup> It should also be noted that ours is a Cournot model with externalities.

---

<sup>7</sup>Price protection rules were introduced to compensate for the potential adverse effects of price fragmentation when the entry of new platforms was encouraged to limit market power of incumbents. In particular, RegNMS requires market centers to route orders at the top of the book to the trading platform that posts the best price, and exchanges to provide accessible electronic data about their price quotations. The aim is to enforce price priority in all markets. However, for large orders execution pricing may not be the same in all exchanges except if traders have in place cross-exchange order-routing technology. In Europe there is no order protection rule similar to RegNMS. Foucault and Menkveld (2008) show empirically the existence of trade-throughs in Amsterdam and London markets. Hendershott and Jones (2005) find that in the US price protection rules improve market quality.

<sup>8</sup>We therefore abstract from competition for order flow issues (see Foucault et al. (2013) for an excellent survey of the topic).

<sup>9</sup>Actually, FD may have to invest on their own also on items such as speed technology. In our model we will abstract from such investments.

<sup>10</sup>See Kreps and Scheinkman (1983) and Vives (1999).

Indeed, gross welfare in our context is *not* given by the integral below the inverse demand curve faced by the exchanges. This is so since platforms' capacity decisions also affect the welfare of market participants other than full dealers (i.e., standard dealers, and liquidity traders).

We now describe in more detail the main features of the model and findings. Due to their ability to trade in both rounds, full dealers exhibit a higher risk bearing capacity compared to standard dealers. As a consequence, an increase in their mass improves market liquidity. This has two countervailing effects on the welfare of market participants. First, it lowers the cost of trading, which leads traders to hedge more aggressively, increasing their welfare. Second, it heightens standard dealers' competitive pressure, lowering their payoffs. As liquidity demand augments for both dealers' classes, however, SD effectively receive a *smaller* share of a *larger* pie. This, in turn, contributes to make *gross* welfare (i.e., the weighted sum of all market participants' welfare) increasing in the proportion of full dealers, implying that liquidity becomes a measurable indicator of gross welfare.

An important feature of the platform competition stage of the model is that dealers' demand for technological services is log-convex for a wide range of deep parameters. Intuitively, when the proportion of full dealers in the market is small, the margin from acquiring the technology to participate in the second round of trade is way larger than in the polar case when the market is almost exclusively populated by full dealers. Thus, an increase in the proportion of full dealers yields a price reduction which becomes increasingly smaller. We show that this has important implications for the nature of exchange competition. In particular, when two platforms are in the market and their marginal costs are small, strategic complementarities in the supply of technological services arise. Hence, a shock that lowers technology costs can prompt a strong response in technological capacity. Furthermore, log-convexity of the demand function can lead a monopoly platform to step up its technological capacity in the face of an entrant. This magnifies the positive impact of an increase in the number of competing platforms on the aggregate technological service capacity. Given that at equilibrium the latter matches the proportion of full dealers, this in turn amplifies the positive liquidity and welfare impact of heightened platform competition.

An insight of our analysis is that technological services can be viewed as an essential intermediate input in the "production" of market liquidity. This warrants a welfare analysis of the impact of platform competition, which is the subject of the last part of the paper. There, we use our setup to compare the market solution arising

with no platform competition (monopoly), and with entry (Cournot free entry), with four different planner solutions which vary depending on the restrictions faced by the planner. An unrestricted planner attains the First Best by choosing the number of competing exchanges as well as the industry technological service fee; a planner who can only regulate the technological service fee but not entry, achieves the Conduct Second Best; finally, if the planner is unable to affect the way in which exchanges compete but can set the number of exchanges who can enter the market, she achieves the Structural Second Best solution (restricted or unrestricted, depending on whether she regulates entry making sure that platforms break even or not).

Insulated from competition, a monopolistic exchange seeks to restrict the supply of technological services to increase the fees it extracts from FD.<sup>11</sup> Thus, the market at a free entry Cournot equilibrium delivers a superior outcome in terms of liquidity and (generally) welfare. However, compared to the case in which the regulator can control entry, the market solution can feature excessive or insufficient entry. Indeed, in the absence of regulation, an exchange makes its entry decision without internalizing the profit reduction it imposes on its competitors. This “profitability depression” effect is conducive to excessive entry. As new platform entry spurs liquidity, however, it also has a positive “liquidity creation” effect which can offset the profitability depression effect, and lead to insufficient entry.<sup>12</sup>

The optimal second best regulatory intervention revolves around a simple trade-off: increasing competition, or lowering the technological service fee, spurs technological capacity production which depresses industry profits to the detriment of exchanges, while increasing liquidity, to the benefit of market participants. When the wedge between First Best and monopolist capacity is sufficiently large, entry regulation is inferior compared to regulating the technological service fee charged by a monopolistic exchange. This is because in this case, to approach the First Best the planner needs to induce a large increase in technological capacity. Due to setup costs, achieving this objective via regulated entry is more costly than forcing the monopolistic exchange to charge the lowest possible technological service fee that is compatible with a break-even

---

<sup>11</sup>In a similar vein, Cespa and Foucault (2014) find that a monopolistic exchange finds it profitable to restrict the access to price data, to increase the fee it extracts from market participants.

<sup>12</sup>These effects are respectively similar to the “business stealing” and “business creation” effects highlighted by the Industrial Organization literature (see Mankiw and Whinston (1986), and Ghosh and Morita (2007)). Note, however, that business stealing refers to the depressing impact that a firm entry has on its competitors’ output. In our context, this effect is not warranted: due to strategic complementarity, heightened competitive pressure can lead an exchange to respond by installing more capacity.

condition. Conversely, when the wedge between monopolist and First Best capacity is small, a smaller increase in technological capacity is required to approach the First Best. In this case the planner may instead choose to regulate entry, since regulating the fee to ensure a monopolist breaks even, leads to a large industry profit depression which is not offset by a sufficiently large market participant welfare gain. We show that the presence of a sector of SD committed to supplying liquidity at each trading round, can increase the demand of technological services and its equilibrium supply, prompting a switch in the optimal second best regulatory approach from fee to entry regulation.

While our analysis suggests conditions under which fee regulation achieves the welfare maximizing provision of technological services, this form of intervention is subject to rent-seeking efforts by market participants. This indicates that entry regulation can at times work as a simpler alternative instrument.<sup>13</sup> Indeed, spurring entry achieves two objectives. First, it works as a corrective against exchanges' market power in the provision of technological services; additionally, by creating competitive pressure, it achieves the objective of keeping exchanges' trading fees in check.

To the best of our knowledge, this paper is the first to analyze the relative merits of different types of regulatory interventions in a single, tractable model of liquidity creation and platform competition in technological services. Our paper is thus related to a growing literature on the effects of platform competition and investment in trading technology. Pagnotta and Philippon (2018), consider a framework where trading needs arise from shocks to traders' marginal utilities from asset holding, yielding a preference for different trading speeds. In their model, venues vertically differentiate in terms of speed, with faster venues attracting more speed sensitive investors and charging higher fees. This relaxes price competition, and the market outcome is inefficient. The entry welfare tension in their case is between business stealing and quality (speed) diversity, like in the models of Gabszewicz and Thisse (1979) and Shaked and Sutton (1982). In this paper, as argued above, the welfare tension arises instead from the profitability depression and liquidity creation effects associated with entry.<sup>14</sup> Biais

---

<sup>13</sup>The evidence presented in footnote 6 suggests that regulators' ability to weigh on the technological fee-setting process is far from perfect.

<sup>14</sup>Pagnotta and Philippon (2018) also study the market integration impact of RegNMS. Pagnotta (2013) studies the interaction between traders' participation decisions and venues' investment in speed technology, analysing the implications of institutions' market power for market liquidity and the level of asset prices. Babus and Parlato (2017) find that market fragmentation arises in equilibrium when the private valuations of different investors are sufficiently correlated. Malamud and Rostek (2017) and Manzano and Vives (2018) look also at whether strategic traders are better off in centralized or

et al. (2015) study the welfare implications of investment in the acquisition of High Frequency Trading (HFT) technology. In their model HFTs have a superior ability to match orders, and possess superior information compared to human (slow) traders. They find excessive incentives to invest in HFT technology, which, in view of the negative externality generated by HFT, can be welfare reducing. Budish et al. (2015) argue that HFT thrives in the continuous limit order book (CLOB), which is however a flawed market structure since it generates a socially wasteful arms' race to respond faster to (symmetrically observed) public signals. The authors advocate a switch to Frequent Batch Auctions (FBA) instead of a continuous market. Budish et al. (2019), introduce exchange competition in Budish et al. (2015) and analyze whether exchanges have incentives to implement the technology required to run FBA. Also building on Budish et al. (2015), Baldauf and Mollner (2017) show that heightened exchange competition has two countervailing effects on market liquidity, since it lowers trading fees, but magnifies the opportunities for cross-market arbitrage, increasing adverse selection. Menkveld and Zoican (2017) show that the impact of a speed enhancing technology on liquidity depends on the news-to-liquidity trader ratio. Indeed, on the one hand, as in our context, higher speed enhances market makers' risk sharing abilities. On the other hand, it increases liquidity providers' exposure to the risk that high frequency speculators exploit their stale quotes. Finally, Huang and Yueshen (2019) analyse speed and information acquisition decisions, assessing their impact on price informativeness, and showing that in equilibrium these can be complements or substitutes. None of the above papers contrasts the impact of different types of regulatory intervention for platforms' investment in technology, market liquidity, and market participants' welfare.

Our paper is also related to the literature on the Industrial Organization of securities' trading. This literature has identified a number of important trade-offs due to competition among trading venues. On the positive side, platform competition exerts a beneficial impact on market quality because it forces a reduction in trading fees (Foucault and Menkveld (2008) and Chao et al. (2019)), and can lead to improvements in margin requirements (Santos and Scheinkman (2001)); furthermore, it improves trading technology and increases product differentiation, as testified by the creation of "dark pools." On the negative side, higher competition can lower the "thick" market externalities arising from trading concentration (Chowdhry and Nanda (1991) and Pagano (1989)), and increase adverse selection risk for market participants

---

segmented markets.

(Dennert (1993)). We add to this literature, by pointing out that market incentives may be insufficient to warrant a welfare maximizing solution. Indeed, heightened competition can lead to the entry of a suboptimal number of trading venues, because of the conflicting impact of entry on profitability and liquidity.

The rest of the paper is organized as follows. In the next section, we outline the model. We then turn our attention to study the liquidity determination stage of the game. In section 4, we analyze the payoffs of market participants, and the demand and supply of technological services. We then concentrate on the impact of platform competition with free entry, and contrast the welfare and liquidity effects of different regulatory regimes. A final section contains concluding remarks.

## 2 The model

A single risky asset with liquidation value  $v \sim N(0, \tau_v^{-1})$ , and a risk-less asset with unit return are exchanged during two trading rounds.

Three classes of traders are in the market. First, a continuum of competitive, risk-averse, “Full Dealers” (denoted by FD) in the interval  $(0, \mu)$ , who are active at both rounds. Second, competitive, risk-averse “Standard Dealers” (denoted by SD) in the interval  $[\mu, 1]$ , who instead are active only in the first round. Finally, a unit mass of traders who enter at date 1, taking a position that they hold until liquidation. At date 2, a new cohort of traders (of unit mass) enters the market, and takes a position. The asset is liquidated at date 3. This liquidity provision model captures in a parsimonious way a setup where all market participants’ trading needs are endogenous, which allows us to perform welfare analysis. In Appendix B and C, we consider two alternative models in which SD enter the market at the second round (Appendix B), or a fixed mass of SD is in the market at both rounds (Appendix C).

### 2.1 Trading venues

The organization of the trading activity depends on the competitive regime among venues. With a monopolistic exchange, both trading rounds take place on the same venue. When platforms are allowed to compete for the provision of technological services, we assume that a best price rule ensures that the price at which orders are executed is the same across all venues. We thus assume away “cross-sectional” frictions, implying that we have a virtual single platform where all exchanges provide identical

access to trading, and stock prices are determined by aggregate market clearing.<sup>15</sup>

We model trading venues as platforms that prior to the first trading round (date 0), supply technology which offers market participants the possibility to trade in the second period. For example, it is nowadays common for exchanges to invest in the supply of co-location facilities which they rent out to traders, to store their servers and networking equipment close to the matching engine; additionally, platforms invest in technologies that facilitate the distribution of market data feeds. In the past, when trading was centralized in national venues, exchanges invested in real estate and the facilities that allowed dealers and floor traders to participate in the trading process.

At date  $t = -1$ , trading venues decide whether to enter and if so they incur a fixed cost  $f > 0$ . Suppose that there are  $N$  entrants, that each venue  $i = 1, 2, \dots, N$  produces a technological service capacity  $\mu_i$ , and that  $\sum_{i=1}^N \mu_i = \mu$ , so that the proportion of FD coincides with the total technological service capacity offered by the platforms. Consistently with the evidence discussed in the introduction (see also Menkveld (2016)), we assume that trading fees are set to the competitive level.

## 2.2 Liquidity providers

A FD has CARA preferences, with risk-tolerance  $\gamma$ , and submits price-contingent orders  $x_t^{FD}$ , to maximize the expected utility of his final wealth:  $W^{FD} = (v - p_2)x_2^{FD} + (p_2 - p_1)x_1^{FD}$ , where  $p_t$  denotes the equilibrium price at date  $t \in \{1, 2\}$ .<sup>16</sup> A SD also has CARA preferences with risk-tolerance  $\gamma$ , but is in the market only in the first period. He thus submits a price-contingent order  $x_1^{SD}$  to maximize the expected utility of his wealth  $W^{SD} = (v - p_1)x_1^{SD}$ . Therefore, FD as SD observe  $p_1$  at the first round; furthermore, FD also observe  $p_2$ , so that their information set at the second round is given by  $\{p_1, p_2\}$ .

The inability of a SD to trade in the second period is a way to capture limited market participation in our model. In today's markets, this friction could be due to technological reasons, as in the case of standard dealers with impaired access to a technology that allows trading at high frequency. In the past, two-tiered liquidity

<sup>15</sup>Holden and Jacobsen (2014) find that in the US, only 3.3% of all trades take place outside the NBBO (NBBO stands for "National Best Bid and Offer," and is a SEC regulation ensuring that brokers trade at the best available ask and bid (resp. lowest and highest) prices when trading securities on behalf of customers). See also Li (2015) for indirect evidence that the single virtual platform assumption is compelling on non-announcement days.

<sup>16</sup>We assume, without loss of generality with CARA preferences, that the non-random endowment of FD and dealers is zero. Also, as equilibrium strategies will be symmetric, we drop the subindex  $i$ .

provision occurred because only a limited number of market participants could be physically present in the exchange to observe the trading process and react to demand shocks.<sup>17</sup>

### 2.3 Liquidity demanders

Liquidity traders have CARA preferences, with risk-tolerance  $\gamma^L$ . In the first period a unit mass of traders enters the market. A trader receives a random endowment of the risky asset  $u_1$  and submits an order  $x_1^L$  in the asset that he holds until liquidation.<sup>18</sup> A first period trader posts a market order  $x_1^L$  to maximize the expected utility of his profit  $\pi_1^L = u_1 v + (v - p_1)x_1^L$ :  $E[-\exp\{-\pi_1^L/\gamma^L\}|u_1]$ . In period 2, a new unit mass of traders enters the market. A second period trader observes  $p_1$  (and can thus perfectly infer  $u_1$ ), receives a random endowment of the risky asset  $u_2$ , and posts a market order  $x_2^L$  to maximize the expected utility of his profit  $\pi_2^L = u_2 v + (v - p_2)x_2^L$ :  $E[-\exp\{-\pi_2^L/\gamma^L\}|p_1, u_2]$ . We assume that  $u_t \sim N(0, \tau_u^{-1})$ ,  $\text{Cov}[u_t, v] = \text{Cov}[u_1, u_2] = 0$ . To ensure that the payoff functions of the liquidity demanders are well defined (see Section 4.1), we impose

$$(\gamma^L)^2 \tau_u \tau_v > 1, \quad (1)$$

an assumption that is common in the literature (see, e.g., Vayanos and Wang (2012)).

### 2.4 Market clearing and prices

Market clearing in periods 1 and 2 is given respectively by  $x_1^L + \mu x_1^{FD} + (1 - \mu) x_1^{SD} = 0$  and  $x_2^L + \mu(x_2^{FD} - x_1^{FD}) = 0$ . We restrict attention to linear equilibria where

$$p_1 = -\Lambda_1 u_1 \quad (2a)$$

$$p_2 = -\Lambda_2 u_2 + \Lambda_{21} u_1, \quad (2b)$$

where the price impacts of endowment shocks  $\Lambda_1$ ,  $\Lambda_2$ , and  $\Lambda_{21}$  are determined in equilibrium. According to (2a) and (2b), at equilibrium, observing  $p_1$  and the sequence  $\{p_1, p_2\}$  is informationally equivalent to observing  $u_1$  and the sequence  $\{u_1, u_2\}$ .

---

<sup>17</sup>Alternatively, we can think of SD as dealers who only trade during the day, and FD as dealers who, thanks to electronic trading, can supply liquidity around the clock.

<sup>18</sup>Recent research documents the existence of a sizeable proportion of market participants who do not rebalance their positions at every trading round (see Heston et al. (2010), for evidence consistent with this type of behavior at an intra-day horizon).

The model thus nests a standard stock market trading model in one of platform competition. Figure 2 displays the timeline of the model.

Figure 2: The timeline.

### 3 Stock market equilibrium

In this section we assume that a positive mass  $\mu \in (0, 1]$  of FD is in the market, and present a simple two-period model of liquidity provision à la Grossman and Miller (1988) where dealers only accommodate endowment shocks but where all traders are expected utility maximizers.

**Proposition 1.** *For  $\mu \in (0, 1]$ , there exists a unique equilibrium in linear strategies in the stock market, where  $x_1^{SD} = -\gamma\tau_v p_1$ ,  $x_1^{FD} = \gamma\tau_u \Lambda_2^{-2}(\Lambda_{21} + \Lambda_1)u_1 - \gamma\tau_v p_1$ ,  $x_2^{FD} = -\gamma\tau_v p_2$ ,  $x_1^L = a_1 u_1$ ,  $x_2^L = a_2 u_2 + b u_1$ , and prices are given by (2a) and (2b),*

$$\Lambda_1 = \left(1 - \left(1 + a_1 + \mu\gamma\tau_u \frac{\Lambda_{21} + \Lambda_1}{\Lambda_2^2}\right)\right) \frac{1}{\gamma\tau_v} > 0 \quad (3a)$$

$$\Lambda_2 = -\frac{a_2}{\mu\gamma\tau_v} > 0 \quad (3b)$$

$$\Lambda_{21} = -(1 - ((1 - \mu)\gamma + \gamma^L)\tau_v \Lambda_1)\Lambda_2 < 0 \quad (3c)$$

$$a_t = \gamma^L \tau_v \Lambda_t - 1 \in (-1, 0) \quad (3d)$$

$$b = -\gamma^L \tau_v \Lambda_{21} \in (0, 1), \quad (3e)$$

and

$$\Lambda_{21} + \Lambda_1 > 0. \quad (4)$$

The coefficient  $\Lambda_t$  in (2a) and (2b) denotes the period  $t$  endowment shock's negative price impact, and is our (inverse) measure of liquidity:

$$\Lambda_t = -\frac{\partial p_t}{\partial u_t}. \quad (5)$$

As we show in Appendix A (see (A.3), and (A.14)), a trader's order is given by

$$\begin{aligned} X_1^L(u_1) &= \underbrace{\gamma^L \frac{E[v - p_1|u_1]}{\text{Var}[v - p_1|u_1]}}_{\text{Speculation}} \underbrace{- u_1}_{\text{Hedging}} \\ X_2^L(u_1, u_2) &= \underbrace{\gamma^L \frac{E[v - p_2|u_1, u_2]}{\text{Var}[v - p_2|u_1, u_2]}}_{\text{Speculation}} \underbrace{- u_2}_{\text{Hedging}}. \end{aligned}$$

According to (3d), a trader speculates and hedges his position to avert the risk of a decline in the endowment value occurring when the return from speculation is low ( $a_t \in (-1, 0)$ ). We will refer to  $|a_t|$  as the trader's "trading aggressiveness." Additionally, according to (3e), second period traders put a positive weight  $b$  on the first period endowment shock. SD and FD provide liquidity, taking the other side of traders' orders. In the first period, standard dealers earn the spread from loading at  $p_1$ , and unwinding at the liquidation price. FD, instead, also speculate on short-term returns. Indeed,

$$x_1^{FD} = \gamma \frac{E[p_2 - p_1|u_1]}{\text{Var}[p_2|u_1]} - \gamma \tau_v p_1.$$

To interpret the above expression, suppose  $u_1 > 0$ . Then, liquidity traders sell the asset, depressing its price (see (2a)) and leading both FD and SD to provide liquidity, taking the other side of the trade. SD hold their position until the liquidation date, whereas FD have the opportunity to unwind it at the second round, partially unloading their inventory risk. Anticipating this, second period traders buy the security (or reduce their short-position), which explains the positive sign of the coefficient  $b$  in their strategy (see (3e)). This implies that  $E[p_2 - p_1|u_1] = (\Lambda_{21} + \Lambda_1)u_1 > 0$ , so that FD anticipate a positive speculative short-term return from going long in the asset.

In sum, FD supply liquidity both by posting a limit order, and a contrarian market

order at the equilibrium price, to exploit the predictability of short term returns.<sup>19</sup> In view of this,  $\Lambda_1$  in (3a) reflects the risk compensation dealers require to hold the portion of  $u_1$  that first period traders hedge and FD do not absorb via speculation:

$$\Lambda_1 = \left( 1 - \left( \underbrace{1 + a_1}_{\text{L1 holding of } u_1} + \underbrace{\frac{\mu\gamma\tau_u(\Lambda_{21} + \Lambda_1)}{\Lambda_2^2}}_{\text{FD aggregate speculative position}} \right) \right) \frac{1}{\gamma\tau_v}.$$

In the second period, liquidity traders hedge a portion  $a_2$  of their order, which is absorbed by a mass  $\mu$  of FD, thereby explaining the expression for  $\Lambda_2$  in (3b).

Therefore, at both trading rounds, an increase in  $\mu$ , or in dealers' risk tolerance, increases the risk bearing capacity of the market, leading to a higher liquidity:

**Corollary 1.** *An increase in the proportion of FD, or in dealers' risk tolerance increases the liquidity of both trading rounds:  $\partial\Lambda_t/\partial\mu < 0$ , and  $\partial\Lambda_t/\partial\gamma < 0$  for  $t \in \{1, 2\}$ .*

According to (2b) and (3c), due to FD short term speculation, the first period endowment shock has a persistent impact on equilibrium prices:  $p_2$  reflects the impact of the imbalance FD absorb in the first period, and unwind to second period traders. Indeed, substituting (3c) in (2b), and rearranging yields:  $p_2 = -\Lambda_2 u_2 + \Lambda_2(-\mu x_1^{FD})$ .

**Corollary 2.** *First period traders hedge the endowment shock more aggressively than second period traders:  $|a_1| > |a_2|$ . Furthermore,  $|a_t|$  and  $b$  are increasing in  $\mu$ .*

Comparing dealers' strategies shows that SD in the first period trade with the same intensity as FD in the second period. In view of the fact that in the first period the latter provide additional liquidity by posting contrarian market orders, this implies that  $\Lambda_1 < \Lambda_2$ , explaining why traders display a more aggressive hedging behavior in the first period. The second part of the above result reflects the fact that an increase in  $\mu$  improves liquidity at both dates, but also increases the portion of the first period endowment shock absorbed by FD. This, in turn, leads second period liquidity traders to step up their response to  $u_1$ .

Summarizing, an increase in  $\mu$  has two effects: it heightens the risk bearing capacity of the market, and it strengthens the propagation of the first period endowment shock

---

<sup>19</sup>This is consistent with the evidence on HFT liquidity supply (Brogaard et al. (2014), and Biais et al. (2015)), and on their ability to predict returns at a short term horizon based on market data (Harris and Saad (2014), and Menkveld (2016)).

to the second trading round. The first effect makes the market deeper, leading traders to step up their hedging aggressiveness. The second effect reinforces second period traders' speculative responsiveness. When all dealers are FD, liquidity is maximal.

## 4 Traders' welfare, technology demand, and exchange equilibrium

In this section we study traders' payoffs, derive demand and supply for technological services, and obtain the platform competition equilibrium.

### 4.1 Traders' payoffs and the liquidity externality

We measure a trader's payoff with the certainty equivalent of his expected utility:  $CE^{FD} \equiv -\gamma \ln(-EU^{FD})$ ,  $CE^{SD} \equiv -\gamma \ln(-EU^{SD})$ ,  $CE_t^L \equiv -\gamma^L \ln(-EU_t^L)$ ,  $t \in \{1, 2\}$ , where  $EU^j$ ,  $j \in \{SD, FD\}$  and  $EU_t^L$ ,  $t \in \{1, 2\}$ , denote respectively the unconditional expected utility of a standard dealer, a full dealer, and a first and second period trader. The following results present explicit expressions for the certainty equivalents.

**Proposition 2.** *The payoffs of a SD and a FD are given by*

$$CE^{SD} = \frac{\gamma}{2} \ln \left( 1 + \frac{\text{Var}[E[v - p_1 | p_1]]}{\text{Var}[v - p_1 | p_1]} \right) \quad (6a)$$

$$CE^{FD} = \frac{\gamma}{2} \left( \ln \left( 1 + \frac{\text{Var}[E[v - p_1 | p_1]]}{\text{Var}[v - p_1 | p_1]} + \frac{\text{Var}[E[p_2 - p_1 | p_1]]}{\text{Var}[p_2 - p_1 | p_1]} \right) + \ln \left( 1 + \frac{\text{Var}[E[v - p_2 | p_1, p_2]]}{\text{Var}[v - p_2 | p_1, p_2]} \right) \right). \quad (6b)$$

*Furthermore:*

1. For all  $\mu \in (0, 1]$ ,  $CE^{FD} > CE^{SD}$ .
2.  $CE^{SD}$  and  $CE^{FD}$  are decreasing in  $\mu$ .
3.  $\lim_{\mu \rightarrow 1} CE^{FD} > \lim_{\mu \rightarrow 0} CE^{SD}$ .

According to (6a) and (6b), dealers' payoffs reflect the accuracy with which these agents anticipate their strategies' unit profits. A SD only trades in the first period, and the accuracy of his unit profit forecast is given by  $\text{Var}[E[v - p_1|p_1]]/\text{Var}[v - p_1|p_1]$  (the ratio of the variance explained by  $p_1$  to the variance unexplained by  $p_1$ ).

A FD instead trades at both rounds, supplying liquidity to first period traders, as a SD, but also absorbing second period traders' orders, and taking advantage of short-term return predictability. Therefore, his payoff reflects the same components of that of a SD, and also features the accuracy of the unit profit forecast from short term speculation ( $\text{Var}[E[p_2 - p_1|p_1]]/\text{Var}[p_2 - p_1|p_1]$ ), and second period liquidity supply ( $\text{Var}[E[v - p_2|p_1, p_2]]/\text{Var}[v - p_2|p_1, p_2]$ ). In sum, as FD can trade twice, benefiting from more opportunities to speculate and share risk, they enjoy a higher expected utility.

Substituting (3d) and (3e) in (6a) and (6b), and rearranging yields:

$$CE^{SD} = \frac{\gamma}{2} \ln \left( 1 + \frac{(1 + a_1)^2}{(\gamma^L)^2 \tau_u \tau_v} \right) \quad (7a)$$

$$CE^{FD} = \frac{\gamma}{2} \left( \ln \left( 1 + \frac{(1 + a_1)^2}{(\gamma^L)^2 \tau_u \tau_v} + \left( \frac{1 + a_1}{1 + \mu \gamma \tau_u \tau_v (\mu \gamma + \gamma^L)} \right)^2 \right) + \ln \left( 1 + \frac{(1 + a_2)^2}{(\gamma^L)^2 \tau_u \tau_v} \right) \right). \quad (7b)$$

An increase in  $\mu$  has two offsetting effects on the above expressions for dealers' welfare. On the one hand, as it boosts market liquidity, it leads traders to hedge more, increasing dealers' payoffs (Corollaries 1 and 2). On the other hand, as it induces more competition to supply liquidity it lowers them. The latter effect is stronger than the former. Importantly, even in the extreme case in which  $\mu = 1$ , a FD receives a higher payoff than a SD in the polar case  $\mu \approx 0$ .

**Proposition 3.** *The payoffs of first and second period traders are given by*

$$CE_1^L = \frac{\gamma^L}{2} \ln \left( 1 + \frac{\text{Var}[E[v - p_1|p_1]]}{\text{Var}[v - p_1|p_1]} + 2 \frac{\text{Cov}[p_1, u_1]}{\gamma^L} \right) \quad (8a)$$

$$CE_2^L = \frac{\gamma^L}{2} \ln \left( 1 + \frac{\text{Var}[E[v - p_2|p_1, p_2]]}{\text{Var}[v - p_2|p_1, p_2]} + \right. \\ \left. 2 \frac{\text{Cov}[p_2, u_2|p_1]}{\gamma^L} + \frac{\text{Var}[E[v - p_2|p_1]]}{\text{Var}[v]} - \left( \frac{\text{Cov}[p_2, u_1]}{\gamma^L} \right)^2 \right). \quad (8b)$$

Furthermore:

1.  $CE_1^L$  and  $CE_2^L$  are increasing in  $\mu$ .
2. For all  $\mu \in (0, 1]$ ,  $CE_1^L > CE_2^L$ .

Similarly to SD, liquidity traders only trade once (either at the first, or at the second round). This explains why their payoffs reflect the precision with which they can anticipate the unit profit from their strategy (see (8a) and (8b)). Differently from SD, these traders are however exposed to a random endowment shock. As a less liquid market increases hedging costs, it negatively affects their payoff ( $\text{Cov}[p_1, u_1] = -\Lambda_1 \tau_u^{-1}$ , and  $\text{Cov}[p_2, u_2|p_1] = -\Lambda_2 \tau_u^{-1}$ ). Finally, (8b) shows that a second period trader benefits when the return he can anticipate based on  $u_1$  is very volatile compared to  $v$  ( $\text{Var}[E[v - p_2|p_1]]/\text{Var}[v]$ ), since this indicates that he can speculate on the propagated endowment shock at favorable prices. However, a strong speculative activity reinforces the relationship between  $p_2$  and  $u_1$ , ( $\text{Cov}[p_2, u_1]^2$ ), leading a trader to hedge little of his endowment shock  $u_2$ , and keep a large exposure to the asset risk, thereby reducing his payoff.

Substituting (3d) and (3e) in (8a) and (8b), and rearranging yields:

$$CE_1^L = \frac{\gamma^L}{2} \ln \left( 1 + \frac{a_1^2 - 1}{(\gamma^L)^2 \tau_u \tau_v} \right) \quad (9)$$

$$CE_2^L = \frac{\gamma^L}{2} \ln \left( 1 + \frac{a_2^2 - 1}{(\gamma^L)^2 \tau_u \tau_v} + \frac{b^2 ((\gamma^L)^2 \tau_u \tau_v - 1)}{(\gamma^L)^4 \tau_u^2 \tau_v^2} \right). \quad (10)$$

An increase in the proportion of FD makes the market more liquid and leads traders to hedge and speculate more aggressively (Corollary 2), benefiting first period traders (Proposition 3). At the same time, it heightens the competitive pressure faced by SD, lowering their payoffs (Proposition 2). As liquidity demand augments for both dealers' classes, however, SD effectively receive a *smaller* share of a *larger* pie. This mitigates the negative impact of increased competition, implying that on balance the positive effect of the increased liquidity prevails:

**Corollary 3.** *The positive effect of an increase in the proportion of FD on first period traders' payoffs is stronger than its negative effect on SD' welfare:*

$$\frac{\partial CE_1^L}{\partial \mu} > -\frac{\partial CE^{SD}}{\partial \mu}, \quad (11)$$

for all  $\mu \in (0, 1]$ .

Aggregating across market participants' welfare yields the following Gross Welfare function:

$$\begin{aligned} GW(\mu) &= \mu CE^{FD} + (1 - \mu) CE^{SD} + CE_1^L + CE_2^L & (12) \\ &= \underbrace{\mu(CE^{FD} - CE^{SD})}_{\text{Surplus earned by FD}} + \underbrace{CE^{SD} + CE_1^L + CE_2^L}_{\text{Welfare of other market participants}} \end{aligned}$$

**Corollary 4.**

1. *The welfare of market participants other than FD is increasing in  $\mu$ .*
2. *Gross welfare is higher at  $\mu = 1$  than at  $\mu \approx 0$ .*

The first part of the above result is a direct consequence of Corollary 3: as  $\mu$  increases, SD's losses due to heightened competition are more than compensated by traders' gains due to higher liquidity. The second part, follows from Proposition 2 (part 3), and Proposition 3. Note that it rules out the possibility that the payoff decline experienced by FD as  $\mu$  increases, leads gross welfare to be higher at  $\mu \approx 0$ . Therefore, a solution that favors liquidity provision by FD is also in the interest of all market participants. Finally, we have:

**Numerical Result 1.** *Numerical simulations show that  $GW(\mu)$  is monotone in  $\mu$ . Therefore,  $\mu = 1$  is the unique maximum of the gross welfare function  $GW(\mu)$ .*

In view of Corollary 1, gross welfare is maximal when liquidity is at its highest level.<sup>20</sup> Furthermore, because of monotonicity, the above market quality indicator, becomes "measurable" welfare indexes.

**Remark 1.** *Our results on liquidity provision and market participants' payoffs are robust to an extension of the model in which a positive mass of standard dealers is in the market at both rounds (see Appendix C).*

<sup>20</sup>Numerical simulations were conducted using the following grid:  $\gamma, \mu \in \{0.01, 0.02, \dots, 1\}$ ,  $\tau_u, \tau_v \in \{1, 2, \dots, 10\}$ , and  $\gamma^L \in \{1/\sqrt{\tau_u \tau_v} + 0.001, 1/\sqrt{\tau_u \tau_v} + 0.101, \dots, 1\}$ , in order to satisfy (1).

## 4.2 The demand for technological services

We define the value of becoming a FD as the extra payoff that such a dealer earns compared to a SD. According to (6a) and (6b), this is given by:

$$\begin{aligned} \phi(\mu) &\equiv CE^{FD} - CE^{SD} && (13) \\ &= \frac{\gamma}{2} \left( \underbrace{\ln \left( 1 + \frac{\text{Var}[E[v - p_1|p_1]]}{\text{Var}[v - p_1|p_1]} + \frac{\text{Var}[E[p_2 - p_1|p_1]]}{\text{Var}[p_2 - p_1|p_1]} \right)}_{\text{Competition}} - \ln \left( 1 + \frac{\text{Var}[E[v - p_1|p_1]]}{\text{Var}[v - p_1|p_1]} \right) \right. \\ &\quad \left. + \ln \left( 1 + \frac{\text{Var}[E[v - p_2|p_1, p_2]]}{\text{Var}[v - p_2|p_1, p_2]} \right) \right)_{\text{Liquidity supply}}. \end{aligned}$$

FD rely on two sources of value creation: first, they compete business away from SD, extracting a larger rent from their trades with first period traders (since they can supply liquidity and speculate on short-term returns); second, they supply liquidity to second period traders.

We interpret the function  $\phi(\mu)$  as the (inverse) demand for technological services as it is the willingness to pay to become a FD.<sup>21</sup>

**Corollary 5.** *The inverse demand for technological services  $\phi(\mu)$  is decreasing in  $\mu$ .*

A marginal increase in  $\mu$  heightens the competition FD face among themselves, and vis-à-vis SD. The former effect lowers the payoff of a FD. In Appendix A, we show that the same holds also for the latter effect. Thus, an increase in the mass of FD erodes the rents from competition, implying that  $\phi(\mu)$  is decreasing in  $\mu$ .

**Numerical Result 2.** *When  $\mu$ ,  $\tau_u$ , and  $\tau_v$  are sufficiently large and  $\gamma$  is large above  $\gamma^L$ ,  $\phi(\mu)$  is log-convex in  $\mu$ :  $(\partial^2 \ln \phi(\mu) / \partial \mu^2) \geq 0$ .*

In Figure 3 (panel (a)) we plot  $\ln(\phi(\mu))$  for a set of parameters yielding log-convexity. When this occurs, the price reduction corresponding to an increase in  $\mu$  becomes increasingly smaller as  $\mu$  increases.<sup>22</sup>

<sup>21</sup>It formalizes in a simple manner the way in which Lewis (2014) describes Larry Tabb's estimation of traders' demand for the high speed, fiber optic connection that Spread laid down between New York and Chicago in 2009.

<sup>22</sup>We checked log-convexity of the function  $\phi(\mu)$ , assuming  $\tau_u, \tau_v \in \{1, 6, 11\}$ ,  $\gamma, \gamma^L \in \{0.01, 0.02, \dots, 1\}$ , and for  $\mu \in \{0.2, 0.4, \dots, 1\}$ . The second derivative of  $\ln(\phi(\mu))$  turns negative for  $\mu$ ,  $\tau_u$ , or  $\tau_v$  low, and for  $\gamma^L > \gamma$  (e.g., this happens when  $\tau_u = 1, \tau_v = 6, \mu = 0.2$ , and  $\gamma^L = 0.41, \gamma = 0.01$ ).

### 4.3 The supply of technological services and exchange equilibrium

Depending on the industrial organization of exchanges, the supply of technological services is either controlled by a single platform, acting as an “incumbent monopolist,” or by  $N \geq 2$  venues who compete à la Cournot in technological capacities. In the former case, the monopolist profit is given by

$$\pi(\mu) = (\phi(\mu) - c)\mu - f, \quad (14)$$

where  $c$  and  $f$ , respectively denote the marginal and fixed cost of supplying a capacity  $\mu$ . We denote by  $\mu^M$  the optimal capacity of the monopolist exchange:  $\mu^M \in \arg \max_{\mu \in (0,1]} \pi(\mu)$ . In the latter case, denoting by  $\mu_i$  and  $\mu_{-i} = \sum_{j \neq i}^N \mu_j$ , respectively the capacity installed by exchange  $i$  and its rivals, and by  $f$  and  $c$  the fixed and marginal cost incurred by an exchange to enter and supply capacity  $\mu_i$ , an exchange  $i$ 's profit function is given by

$$\pi(\mu_i, \mu_{-i}) = (\phi(\mu) - c)\mu_i - f. \quad (15)$$

With  $N \geq 2$  venues we may assume that dealers are distributed uniformly across the exchanges and that competition among exchanges proceeds in a two-stage manner. First each exchange sets its capacity (and this determines how many dealers become FD in the venue) and then exchanges compete in prices. This two stage game is known to deliver Cournot outcomes under some mild conditions (Kreps and Scheinkman (1983)). We define a symmetric Cournot equilibrium as follows:

**Definition 1.** *A symmetric Cournot equilibrium in technological service capacities is a set of capacities  $\mu_i^C \in (0, 1]$ ,  $i = 1, 2, \dots, N$ , such that (i) each  $\mu_i^C$  maximizes (15), for given capacity choice of other exchanges  $\mu_{-i}^C$ :  $\mu_i^C \in \arg \max_{\mu_i} \pi(\mu_i, \mu_{-i}^C)$ , (ii)  $\mu_1^C = \mu_2^C = \dots = \mu_N^C$ , and (iii)  $\sum_{i=1}^N \mu_i^C = \mu^C(N)$ .*

We have the following result:

**Proposition 4.** *There exists at least one symmetric Cournot equilibrium in technological service capacities and no asymmetric ones.*

**Proof.** See Amir (2018), Proposition 7, and Vives (1999), Section 4.1. □

Numerical simulations show that the equilibrium is unique and stable.<sup>23</sup>

### 4.3.1 Strategic complementarity in capacity decisions

With Cournot competition, log-convexity of the inverse demand function implies that the (log of the) revenue of an exchange displays increasing differences in the pair  $(\mu_i, \mu_{-i})$ . Indeed,  $\ln(\phi(\mu_i, \mu_{-i})\mu_i) = \ln(\phi(\mu_i, \mu_{-i})) + \ln \mu_i$ , and  $\ln(\phi(\mu_i, \mu_{-i}))$  has increasing differences in  $(\mu_i, \mu_{-i})$  since this is equivalent to  $\phi$  being log-convex.

Thus, with a zero marginal cost, a larger capacity installed by rivals has a negative impact on an exchange profit which decreases in the exchange capacity choice. This leads a platform to respond to an increase in its rivals' capacity choice by increasing the capacity it installs (in this situation a Cournot oligopoly is a game of strategic complements, see e.g., Amir (2018), Proposition 3). This is because when FD demand is log-convex, the intensive margin effect of a capacity increase is more than offset by the corresponding extensive margin effect. Hence, a platform's decision to step up capacity in the face of rivals' capacity increase, induces a mild price decline that is more than compensated by the exchange increase in market share, allowing the platform to boost its revenue (and cut its losses). By continuity, when the marginal cost is sufficiently small, log-convexity of  $\phi(\mu)$  can make an exchange best response  $BR(\mu_{-i}) = \arg \max_{\mu_i} \{\pi(\mu_i, \mu_{-i}) | \mu_i \in (0, 1]\}$ , increasing in its rivals' choices (see Figure 3, panel (b)).<sup>24</sup>

**Numerical Result 3.** *When  $N = 2$ , strategic complementarities in capacity decisions can arise for some range of exchanges' best response.*

For example, assuming a low value for the marginal cost ( $c = 0.0002$ ), the model easily displays strategic complementarities (see Figure 3, panel (b)).

For  $N > 2$  (when  $c > 0$ , albeit small) we find instead that an exchange's best response is downward sloping. At a symmetric Cournot equilibrium, we have:

$$\left. \frac{\partial BR_i(\mu_{-i})}{\partial \mu_{-i}} \right|_{\mu=\mu^C(N)} = - \frac{\phi''(\mu)(\mu/N) + \phi'(\mu)}{\phi''(\mu)(\mu/N) + 2\phi'(\mu)} \Big|_{\mu=\mu^C(N)}. \quad (16)$$

<sup>23</sup>In our setup, a sufficient condition for stability (Section 4.3 in Vives (1999)) is that the elasticity of the slope of the FD inverse demand function is bounded by the number of platforms (plus one):  $\mathcal{E}|_{\mu=\mu^C(N)} \equiv -\mu\phi''(\mu)/\phi'(\mu)|_{\mu=\mu^C(N)} < 1 + N$ .

<sup>24</sup>Parameter values are consistent with Leland (1992).

$$c = 0.0002, \gamma = 0.5, \gamma^L = 0.25, \tau_u = 100, \tau_v = 3$$

Figure 3: Log-convexity of the demand function (Panel (a)), and strategic complementarities in platforms' capacity decisions (Panel (b)).

As  $N$  increases, the platform's marginal gain in market share from a capacity increase shrinks (the weight of the positive effect due to demand convexity in (16) declines), yielding a negatively sloped best response.

#### 4.3.2 Comparative statics with respect to $N$

At a stable Cournot equilibrium, standard comparative statics results apply (see, e.g., Section 4.3 in Vives (1999)). In particular, an increase in the number of exchanges leads to an increase in the aggregate technological service capacity, and a decrease in each exchange profit:

$$\frac{\partial \mu^C(N)}{\partial N} \geq 0 \quad (17a)$$

$$\left. \frac{\partial \pi_i(\mu)}{\partial N} \right|_{\mu=\mu^C(N)} \leq 0. \quad (17b)$$

If the number of competing platforms is exogenously determined, condition (17a) implies that spurring competition in the intermediation industry has positive effects in terms of liquidity and gross welfare (Proposition 1 and Numerical Result 1):

**Corollary 6.** *At a stable Cournot equilibrium, an exogenous increase in the number of competing exchanges has a positive impact on liquidity and gross welfare:  $\partial \Lambda_t / \partial N < 0$ ,  $\partial GW / \partial N > 0$ .*

Degryse et al. (2015) study 52 Dutch stocks in 2006-2009 (listed on Euronext Amsterdam and trading on Chi-X, Deutsche Börse, Turquoise, BATS, Nasdaq OMX and SIX Swiss Exchange) and find a positive relationship between market fragmentation (in terms of a lower Herfindhal index, higher dispersion of trading volume across exchanges) and the *consolidated liquidity* of the stock. Foucault and Menkveld (2008) also find that consolidated liquidity increased when in 2004 the LSE launched EuroSETS, a new limit order market to allow Dutch brokers to trade stocks listed on Euronext (Amsterdam).

Upward sloping best responses can lead a platform to respond to a heightened competitive pressure, with an increase in installed capacity, strengthening the aggregate effect in (17a), and the resulting impact this has on liquidity and gross welfare.<sup>25</sup> To illustrate this effect, in Figure 4 we use the same parameters of Figure 3 (panel (b)), and study the impact of an increase in competition. Panel (a) in the figure shows that platforms step up their individual capacity, with a positive effect on liquidity (panels (b) and (c)), and welfare (panel (d)).

## 5 Endogenous platform entry and welfare

In this section we endogenize platform entry, and study its implications for welfare and market liquidity.<sup>26</sup> Assuming that platforms' technological capacities are identical ( $\mu = N\mu_i$ ), a social planner who takes into account the costs incurred by the exchanges faces the following objective function:

$$\begin{aligned} \mathcal{P}(\mu, N) &\equiv GW(\mu) - c\mu - fN \\ &= \pi(\mu_i)N + \psi(\mu). \end{aligned} \tag{18}$$

Expression (18) is the sum of two components. The first component reflects the profit generated by competing platforms, who siphon out FD surplus, and incur the costs associated with running the exchanges:  $\pi(\mu_i)N = ((\phi(\mu) - c)\mu_i - f)N$ , implying that

---

<sup>25</sup>The necessary and sufficient condition for an increase in  $N$  to lead to an increase in individual capacity is that  $N < \mathcal{E}|_{\mu=\mu^c} < 1 + N$  (see Section 4.3 in Vives (1999)).

<sup>26</sup>For example, according to the UK Competition Commission (2011), a platform entry fixed cost covers initial outlays to acquire the matching engine, the necessary IT architecture to operate the exchange, the contractual arrangements with connectivity partners that provide data centers to host and operate the exchange technology, and the skilled personnel needed to operate the business. The Commission estimated that in 2011 this roughly corresponded to £10-£20 million.

Figure 4: Effect of entry on each platform capacity decisions (panel (a)), liquidity (panels (b) and (c)), and gross welfare (panel (d)) (parameter values as in Figure 3).

FD surplus only contributes indirectly to the planner’s function, via platforms’ total profit. The second component in (18) reflects the welfare of other market participants:  $\psi(\mu) = CE^{SD} + CE_1^L + CE_2^L$ , and highlights the welfare effect of technological capacity choices via the liquidity externality.<sup>27</sup> We consider five possible outcomes:

1. Cournot with free entry (CFE). In this case, we look for a symmetric Cournot equilibrium in  $\mu$ , as in Definition 1, and impose the free entry constraint:

$$(\phi(\mu^C(N)) - c)\frac{\mu^C(N)}{N} \geq f > (\phi(\mu^C(N+1)) - c)\frac{\mu^C(N+1)}{N+1}, \quad (19)$$

<sup>27</sup>Even incumbent exchanges may have to incur an entry cost to supply liquidity in the second round. For example, faced with increasing competition from alternative trading venues, in 2009 LSE decided to absorb Turquoise, a platform set up about a year before by nine of the world’s largest banks. (See “LSE buys Turquoise share trading platform,” *Financial Times*, December 2009).

which pins down  $N$ . We denote by  $\mu^{CFE}$ , and  $N^{CFE}$  the pair that solves the Cournot case. Note that, given Proposition 4 and (17b), a unique Cournot equilibrium with free entry obtains in our setup if (17b) holds and for a given  $N$  the equilibrium is unique.

2. Structural Second Best (ST). In this case we posit that the planner can determine the number of exchanges that operate in the market. As exchanges compete à la Cournot in technological capacities, we thus look for a solution to the following problem:  $\max_{N \geq 1} \mathcal{P}(\mu^C(N), N)$  s. t.  $\mu^C(N)$  is a Cournot equilibrium with  $\pi_i^C(N) \geq 0$ , and denote by  $\mu^{ST}$ , and  $N^{ST}$  the pair that solves the planner's problem.
3. Unrestricted Structural Second Best (UST). In this case we relax the non-negativity constraint in the STR, assuming that the planner can make side-payments to exchanges if they do not break-even, and look for a solution to the following problem:  $\max_{N \geq 1} \mathcal{P}(\mu^C(N), N)$  s. t.  $\mu^C(N)$  is a Cournot equilibrium, and denote by  $\mu^{UST}$ , and  $N^{UST}$  the pair that solves the planner's problem.
4. Conduct Second Best (CO). In this case, we let the planner set the fee that exchanges charge to FD, assuming free entry of platforms. Because of Corollary 5,  $\phi(\mu)$  is invertible in  $\mu$ , implying that setting the fee is equivalent to choosing the aggregate technological capacity  $\mu$ . Thus, we look for a solution to the following problem:

$$\max_{\mu \in (0,1]} \mathcal{P}(\mu, N) \text{ s.t. } (\phi(\mu) - c) \frac{\mu}{N} \geq f \geq (\phi(\mu) - c) \frac{\mu}{N+1}, \quad (20)$$

and denote by  $\mu^{CO}$  and  $N^{CO}$  the pair that solves (20).<sup>28</sup>

5. First Best (FB). In this case, we assume that the planner can regulate the market choosing the fee and the number of competing platforms:  $\max_{\mu \in (0,1], N \geq 1} \mathcal{P}(\mu, N)$ . We denote by  $\mu^{FB}$  and  $N^{FB}$  the pair that solves the planner's problem.

We contrast the above four cases with the “Unregulated Monopoly” outcome (M) defined in Section 4.3, focusing on welfare and market liquidity (we state our results in terms of aggregate technological capacity  $\mu$ , with the understanding that based on Corollary 1, a higher technological capacity implies a higher liquidity). We make the maintained assumptions that both the monopoly profit and  $\mathcal{P}(\mu, 1)$  are single-peaked

---

<sup>28</sup>We assume for simplicity that if the second inequality holds with equality, then only  $N$  firms enter.

in  $\mu$ , with maximum monopoly profit being positive, and that the Cournot equilibrium is stable.<sup>29</sup>

## 5.1 First Best vs. market solutions

We start by comparing the First Best (FB) outcome with the two polar market solutions of Monopoly (M) and Cournot Free Entry (CFE). We obtain the following result:

**Proposition 5.** *At the First Best the planner sets  $N^{FB} = 1$ . Furthermore:*

1. *If the monopoly solution is interior ( $\mu^M \in (0, 1)$ ), then  $\mu^{FB} > \mu^M$ .*
2. *If at the First Best the monopoly profit is non-positive ( $\pi^M(\mu^{FB}) \leq 0$ ), then  $\mu^{FB} > \mu^{CFE} \geq \mu^M$ .*
3. *Welfare comparison:  $\mathcal{P}^{FB}$  is larger than both  $\mathcal{P}^{CFE}$  and  $\mathcal{P}^M$ .*

At the First Best, the planner minimizes entry costs by letting a single exchange satisfy the industry demand for technological services. If at the First Best the monopoly profit is non-positive, then aggregate capacity must be strictly larger than the one at the Cournot Free Entry outcome since otherwise platforms would make negative profits. Furthermore, the capacity supplied at the monopoly outcome can be no larger than the one obtained with Cournot Free Entry since, under Cournot stability, increased platform entry leads to increased technological service capacity. Finally, with higher technological service capacity, and minimized fixed costs, the First Best solution is superior to either market outcome.

We can compare  $\mu^{FB}$  with the capacity that obtains if the fixed cost tends to zero, and thus the number of platforms grows unboundedly at the CFE. In this case, platforms become price takers ( $PT$ ), and the implied aggregate capacity is implicitly defined by:  $\phi(\mu^{PT}) = c$ . Since  $\mathcal{P} = (\phi(\mu) - c)\mu + \psi(\mu)$ , we have that  $\mathcal{P}' = \phi(\mu) - c + \mu\phi'(\mu) + \psi'(\mu)$  and therefore:

$$\left. \frac{\partial \mathcal{P}}{\partial \mu} \right|_{\mu=\mu^{PT}} = \mu^{PT} \phi'(\mu^{PT}) + \psi'(\mu^{PT}), \quad (21)$$

which will be positive or negative depending on whether the cost to the industry of marginally increasing capacity ( $-\mu^{PT} \phi'(\mu^{PT})$ ) is smaller or larger than the marginal

---

<sup>29</sup>These conditions are satisfied in all of our simulations (see Table 3).

benefit to the other market participants ( $\psi'(\mu^{PT})$ ). At  $\mu^{PT}$  exchanges do not internalize either effect and only in knife-edge cases we will have that  $\mu^{FB} = \mu^{PT}$ .<sup>30</sup>

## 5.2 Fee regulation

We now compare the constrained second best optimum the planner achieves with conduct (fee) regulation (CO) with the two polar market solutions. Under the assumption that the monopoly profit is negative at the First-Best solution, which implies that at the CO profits are exactly zero (see Lemma A.2 in Appendix A), we obtain the following result:

**Proposition 6.** *When the planner regulates the technological service fee, if at the First Best the monopoly profit is negative,*

1.  $N^{CO} = 1$ .
2. *The technological service capacity supplied at the CO is lower than at the FB but higher than at the CFE:  $\mu^{FB} > \mu^{CO} > \mu^{CFE}$ .*
3. *Welfare ranking:  $\mathcal{P}^{FB} > \mathcal{P}^{CO} > \mathcal{P}^{CFE}$ .*

Suppose that at the First Best the monopoly profit is negative.<sup>31</sup> Then with fee regulation (CO), the aggregate technological capacity should be smaller than at the First Best since otherwise the platforms would make negative profits. As for a given (aggregate)  $\mu$  the profit of an exchange is decreasing in  $N$ , for given  $\mu$  the maximum profit obtains when  $N = 1$  implying that  $N^{CO} = 1$ . Furthermore, given that  $\mathcal{P}$  is single peaked in  $\mu$ , it is optimal for  $\mu^{CO}$  to be set as large as possible so that profits are zero. Finally, with fee regulation, one platform breaks even, while at a Cournot Free Entry (i) a single platform makes a positive profit (recall that monopoly profits are assumed to be positive), and (ii) if more than one platform is in the market, then platforms lose money when offering a capacity larger or equal to the one obtained with fee regulation. In either case,  $\mu^{CFE} < \mu^{CO}$ , and we have:  $\mu^{CFE} < \mu^{CO} < \mu^{FB}$ .<sup>32</sup>

---

<sup>30</sup>Note, however, that if the welfare of other market participants is constant, then the monopoly solution implements the First Best.

<sup>31</sup>We have numerically verified the above sufficient condition for  $N^{CO} = 1$ , and found that in our simulations it is always satisfied. In the reverse order of actions model, in some cases  $\pi^M(\mu^{CO}) > 0$ , but the planner still sets  $N^{CO} = 1$ . See Table 2 for details.

<sup>32</sup>More precisely, notice that  $\mu^{CFE}$  cannot be higher than  $\mu^{CO}$ , as at  $\mu^{CO}$  one firm makes zero profit. Thus, given single-peakedness of the monopoly profit, if there is either one or more than one

**Remark 2.** *If at the First Best the monopoly profit is positive, two cases can arise. First, we can have that  $(\phi(\mu^{FB}) - c)\mu^{FB}/2 - f \leq 0$ , in which case both constraints of the Conduct Second Best problem are satisfied at  $(\mu^{CO}, N^{CO}) = (\mu^{FB}, 1)$ , and the Conduct Second Best implements the First Best outcome. If, on the other hand, two platforms earn a positive profit at the First Best— $(\phi(\mu^{FB}) - c)\mu^{FB}/2 - f > 0$ —then at a Conduct Second Best the planner needs to set a lower fee for technological services compared to the one of the First Best and/or allow more than one platform to enter the market. Indeed, if  $N^{CO} = 1$ , then by construction  $\mu^{CO}$  cannot be set smaller than  $\mu^{FB}$  since this would violate the right constraint of the Conduct Second Best problem.*

### 5.3 Entry regulation

Regulating the fee can however be complicated, as our discussion in the introduction suggests. Thus, we now focus on the case in which the planner can only decide on the number of competing exchanges. In the absence of regulation, a Cournot equilibrium with free entry arises (see (19)), and we compare this outcome to the Structural Second Best, in both the unrestricted and restricted cases. Evaluating the first order condition of the planner at  $N = N^{CFE}$  (ignoring the integer constraint) yields:

$$\begin{aligned} \frac{\partial \mathcal{P}(\mu^C(N), N)}{\partial N} \Big|_{N=N^{CFE}} &= \underbrace{\pi_i(\mu^C(N), N)}_{=0} \Big|_{N=N^{CFE}} & (22) \\ &+ N^{CFE} \underbrace{\frac{\partial \pi_i(\mu^C(N), N)}{\partial N}}_{\text{Profitability depression} < 0} \Big|_{N=N^{CFE}} \\ &+ \underbrace{\psi'(\mu) \frac{\partial \mu^C(N)}{\partial N}}_{\text{Liquidity creation} > 0} \Big|_{N=N^{CFE}}. \end{aligned}$$

According to (22), at a stable Cournot equilibrium, entry has two countervailing welfare effects.<sup>33</sup> The first one is a “profitability depression” effect, and captures the profit

---

firm in the CFE with  $\mu^{CFE} > \mu^{CO}$ , profits will be negative. Similarly, it cannot be  $\mu^{CFE} = \mu^{CO}$  because if  $N^{CFE} = 1$  then  $\mu^{CO} = \mu^{CFE} = \mu^M$ , and by assumption the monopoly profit is positive; if, instead,  $N^{CFE} > 1$ , then more than one firm shares the revenue that one firm has in the CO solution, so that its profit must be negative.

<sup>33</sup>This is because at a stable equilibrium (17a) and (17b) hold, see section 4.3 in Vives (1999).

decline associated with the demand reduction faced by each platform as a result of entry. This effect is conducive to excessive entry, as each competing exchange does not internalize the negative impact of its entry decision on competitors' profits. The second one is a "liquidity creation" effect and reflects the welfare creation of an increase in  $N$  via the liquidity externality. This effect is conducive to insufficient entry since each exchange does not internalize the positive impact of its entry decision on other market participants' payoffs.

The above effects are related to the ones arising in a Cournot equilibrium with free entry (Mankiw and Whinston (1986) and Ghosh and Morita (2007)). Liquidity creation is akin to the "business creation" effect (i.e., *total* output increases in the number of firms) highlighted by Ghosh and Morita (2007) in their analysis of entry in a vertical oligopoly setting. This effect can overturn the traditional "excessive-entry" result of the standard Cournot setting that Mankiw and Whinston (1986) trace to the profitability depression due to "business stealing" (i.e., *individual* output decreases in the number of firms).

In our setup, when we compare  $N^{CFE}$  with  $N^{ST}$ , entry is always excessive (as in Mankiw and Whinston (1986)); however, when  $N^{CFE}$  is stacked against  $N^{UST}$ , this conclusion does not necessarily hold. More in detail,  $N^{CFE}$  is the the largest  $N$  so that platforms break even at a Cournot equilibrium. At the STR solution, platforms break even too, but the planner internalizes the profitability depression effect of entry. Thus, we have that  $N^{CFE} \geq N^{ST}$ . Conversely, removing the break even constraint, the planner achieves the Unrestricted STR and, depending on which of the effects outlined above prevails, both excessive or insufficient entry can occur:

**Proposition 7.** *When the planner regulates entry, for stable Cournot equilibria:*

1.  $N^{CFE} \geq N^{ST}$ ,  $\mu^{CFE} \geq \mu^{ST}$ .
2. *When the profitability depression effect is stronger than the liquidity creation effect,  $N^{CFE} \geq N^{UST}$ ,  $\mu^{CFE} \geq \mu^{UST}$ . Otherwise, the opposite inequalities hold.*
3. *The technological capacity at CFE is higher than at STR, which is in turn higher than at M:  $\mu^{CFE} \geq \mu^{ST} \geq \mu^M$ . The technological capacity at UST is higher than at M:  $\mu^{UST} \geq \mu^M$ .*
4. *Welfare ranking:  $\mathcal{P}^{FB} \geq \mathcal{P}^{UST} \geq \mathcal{P}^{ST} \geq \mathcal{P}^{CFE}$ .*

The first two items in the proposition reflect our previous discussion. Item 3 shows that while the technological capacity offered with free platform entry (CFE) is higher than at the Structural Second Best (a natural consequence of excessive entry with respect to the STR benchmark), when the planner relaxes the break-even constraint (UST), the comparison is inconclusive. Indeed, as explained above, to exploit the positive liquidity externality, the planner may favor entry beyond the break-even level—subsidising the loss-making platforms. Thus, while entry regulation implies that liquidity maximization is generally at odds with welfare maximization, the two may be aligned when the planner is ready to make up for platforms’ losses. Finally, as at the UST the non-negativity constraint of the exchanges’ profit is relaxed,  $\mathcal{P}^{UST} \geq \mathcal{P}^{ST}$  must hold.

To verify the possibility of excessive or insufficient entry compared to the UST, we run two sets of numerical simulations. In the first set, as in Figure 3 we assume standard risk aversion ( $\gamma = 0.5$ ,  $\gamma^L = 0.25$ ), a 10% annual volatility for the endowment shock, and consider a “high” and a “low” payoff volatility scenario (respectively,  $\tau_v = 3$ , which which corresponds to a 60% annual volatility for the liquidation value, and  $\tau_v = 25$  which corresponds to a 20% annual volatility). Platform costs are set to  $f \in \{1 \times 10^{-6}, 2 \times 10^{-6}, \dots, 31 \times 10^{-6}\}$ , and  $c = 0.002$ .<sup>34</sup> In the second set, we assume lower values for risk aversion ( $\gamma = 25$ ,  $\gamma^L = 12$ ) which are consistent with the literature on price pressure, and recent results on the structural estimation of risk aversion based on insurance market data,<sup>35</sup> and set  $\tau_v = \tau_u = 0.1$  (corresponding to a 316% annual volatility for both the endowment shock and the liquidation value),  $f \in \{1 \times 10^{-2}, 2 \times 10^{-2}, \dots, 31 \times 10^{-2}\}$ , and  $c = 2$ . For both sets of simulations, we solve for the technological capacity and the number of platforms, in both the “Original” and “Reverse” order of actions cases, (respectively, OO and RO), and perform robustness analysis (see Tables 2 and 3).

**Numerical Result 4.** *The results of our numerical simulations are as follows:*

1. *With standard risk aversion values:*

(a) *With high payoff volatility, entry is excessive:  $N^{CFE} > N^{UST}$ , and  $\mu^{CFE} > \mu^{UST}$ .*

---

<sup>34</sup>Analyzing the US market, Jones (2018) argues that barriers to entry to the intermediation industry are very low, a consideration that is corroborated by the current state of the market, where 13 cash equity exchanges compete with over 30 ATS. This suggests that entry cost must be low.

<sup>35</sup>See respectively Hendershott and Menkveld (2014), and Cohen and Einav (2007).

(b) *With low payoff volatility, when the marginal cost of technological capacity is low, and for sufficiently large values of the entry cost, entry is insufficient:  $N^{CFE} < N^{UST}$  and  $\mu^{CFE} < \mu^{UST}$ .*

2. *With low risk aversion values, for sufficiently large values of the entry cost, entry is insufficient.*

Furthermore, at all solutions  $N$  and  $\mu$  are decreasing in  $f$ .<sup>36</sup>

Figure 5 illustrates the output of two simulations in which insufficient entry occurs (when  $c = 0.005$ , a case we do not display, insufficient entry disappears). Insufficient entry implies that platforms enjoy stronger market power compared to a social planner objective. This situation appears to be in line with the complaints raised by many market participants, as we argue in the introduction, but also with the view of some regulators.<sup>37</sup>

## 5.4 Comparing all solutions

The previous sections have shown that either fee regulation (Section 5.2) or entry/merger policy (Section 5.3) can be used as a tool to correct platforms' market power, and improve aggregate welfare. The following result assesses which one of such tools works best:

**Proposition 8.** *Comparing solutions when  $\pi^M(\mu^{FB}) < 0$ :*

1.  $\mu^{FB} > \mu^{CO} > \mu^{CFE} \geq \mu^{ST} \geq \mu^M$ .
2. *The number of exchanges entering the market with Cournot free entry or with entry regulation is no lower than with fee regulation ( $N^{CO} = 1$ ).*
3. *Welfare comparison:*

$$\mathcal{P}^{FB} > \mathcal{P}^{CO} > \mathcal{P}^{ST} \geq \max\{\mathcal{P}^{CFE}, \mathcal{P}^M\} \geq \min\{\mathcal{P}^{CFE}, \mathcal{P}^M\}, \quad (23a)$$

$$\mathcal{P}^{FB} \geq \mathcal{P}^{UST} \geq \mathcal{P}^{ST}, \quad (23b)$$

---

<sup>36</sup>Assuming  $\gamma = 0.25 < \gamma^L = 0.5$  yields qualitatively similar results in the high volatility case, whereas in the low volatility case insufficient entry disappears.

<sup>37</sup>“[...] For example, one exchange, EDGX, has raised the price on its standard 10GB connection five times since 2010—in total, leaving the price of the connection seven times higher than it was in that year.” *Unfair Exchange: The State of America's Stock Markets*, speech of Commissioner Robert J. Jackson Jr., George Mason University, September 2018.

where if the *FB* solution is interior, then  $\mathcal{P}^{FB} > \mathcal{P}^{UST}$ .

The first two items in the proposition respectively follow from Propositions 5, 6, and 7, and from Propositions 6, and 7.

In terms of welfare, due to Propositions 5, and 6, the First Best outcome is superior to the one achieved with fee regulation, which is in turn preferred to the monopoly outcome. Since  $\mu^{ST} \leq \mu^{CFE} < \mu^{CO} < \mu^{FB}$ —so that we are in the increasing (in  $\mu$ ) part of the planner’s objective function—and  $N^{ST} \geq 1 = N^{CO}$ , we have that fee regulation is also superior to entry/merger policy (constrained by the break even condition). In words: with entry policy the planner allows platforms to retain some market power, to make up for the entry cost. However, if the planner can regulate the fee, provided that aggregate capacity at a constrained second best solution falls short of that implied by the First Best, a superior outcome can be achieved in terms of liquidity, which also allows to save on setup costs. Finally, entry policy (with the break-even constraint) yields an outcome that is never inferior in terms of welfare to the polar market solutions (CFE and M). Indeed, the latter are always available to the planner.

The results under the assumption of Proposition 8 imply that, if unregulated, the monopoly outcome yields lower liquidity compared to any other alternative. Furthermore, in our simulations, the planner’s objective function evaluated at  $\mu^M$  is always the lowest compared to the other five alternatives. Thus, both from a liquidity, and welfare point of view the unregulated monopoly solution is the worst possible.

## 5.5 The effect of “committed” SD

In the liquidity provision model of Section 3, only FD can supply liquidity to second period traders. This is a convenient assumption which however fails to recognize that in actual markets liquidity provision is ensured by a multitude of market participants. In this section we check how the introduction of a mass of “committed” SD, present in the market at each trading round, can alter the risk-sharing properties of the market, affecting exchanges’ technology supply, and the welfare ranking among different forms of regulatory intervention.

Suppose that a mass  $\epsilon$  of SD is unable to become FD and is in the market at each trading round, so that in total, a mass  $2\epsilon$  SD are committed. Thus, at the first round liquidity is supplied by  $\mu$  FD, and a total mass  $1 - \mu$  of SD ( $\epsilon$  of which are committed,

and  $1 - \epsilon - \mu$  are as in the baseline model). At the second round, instead, we have a total mass of  $\mu$  FD and  $\epsilon$  SD liquidity suppliers (see Figure C.1 in Appendix C for the modified timeline of the model). In the following, we summarize the effect of committed dealers in the model, and refer the interested reader to Appendix C for a detailed analysis. With committed dealers the market clearing equations in Section 2.4 are replaced by:  $\mu x_1^{FD} + (1 - \mu)x_1^{SD} + x_1^L = 0$ , and  $(x_2^{FD} - x_1^{FD})\mu + \epsilon x_2^{SD} + x_2^L = 0$ , where  $x_2^{SD}$  denotes the position of a committed dealer at the second round (see (C.5)). Thus, denoting by  $\tilde{\Lambda}_t$ ,  $\tilde{\Lambda}_{21}$ ,  $\tilde{a}_t$ , and  $\tilde{b}$  the coefficients of the linear equilibrium with committed dealers (which replace the corresponding price coefficients in (2a), (2b), and traders' strategies in Proposition 1), in Appendix C we prove the following result:

**Proposition 9.** *For  $\mu \in [0, 1]$ , there exists a unique equilibrium in linear strategies in the stock market where a mass  $\epsilon$  of SD is in the market at both rounds. At equilibrium, the sign of the comparative statics effect of  $\mu$ , as well as the ranking between liquidity traders' hedging aggressiveness is preserved, while*

1.  $\tilde{\Lambda}_t$ ,  $|\tilde{a}_t|$  are respectively decreasing and increasing in  $\epsilon$ .
2.  $|\tilde{\Lambda}_{21}|$  and  $\tilde{b}$  are decreasing in  $\epsilon$ .

Committed dealers improve the risk bearing capacity of the market, increasing its liquidity at both rounds, and leading traders to hedge a larger fraction of their endowment shock. As second period traders face heightened competition in speculating against the propagated endowment shock, a larger  $\epsilon$  reduces their response to  $u_1$  ( $\tilde{b}$ ).

To measure the impact on the welfare of market participants and the market for technological services, we appropriately replace the equilibrium coefficients with their tilde-ed counterparts in the expressions for the market participants' payoffs (see (6a), (6b), (8a), and (8b)), and compute the payoff for second period committed dealers (see (C.15)) which, given Proposition 9, is decreasing in  $\mu$ . Finally, defining the inverse demand for technological services as the payoff difference between FD and first period dealers:  $\phi(\mu) \equiv CE^{FD} - CE_1^{SD}$ , we also obtain the following result:

**Corollary 7.** *With committed SD:*

1. *The comparative statics effect of  $\mu$  on dealers' and traders' payoffs, and the inverse demand for technological services, are as in Propositions 2, 3, and Corollary 5. Furthermore, the payoff of second period committed dealers is decreasing in  $\mu$ .*

2. Standard dealers' payoffs are decreasing in  $\epsilon$ .

Committed dealers heighten competition in the provision of liquidity, explaining the second part of Corollary 7. Numerical simulations show that an increase in  $\epsilon$  increases the payoff of liquidity traders at both rounds as well as that of FD. The former effect is in line with the improved liquidity provision enjoyed by liquidity traders. The intuition for the latter is that besides the competitive effect, committed dealers also improve FD ability to share risk when they retrade at the second period. This also explains why in our simulations, the demand for technological services can be non-monotone in  $\epsilon$ , as shown in Figure 6.

More in detail, the demand for technological services can increase (decrease) with a higher  $\epsilon$  in the low (high) payoff volatility scenario. This is consistent with the fact that an increase in  $\tau_v$  leads first period traders to hedge a larger portion of their endowment, increasing FD risk exposure, and thereby increasing the value of technological services to this class of liquidity providers. Indeed, based on (C.7b) and (C.12),  $\tilde{a}_1 < 0$ , and we have  $\partial \tilde{a}_1 / \partial \tau_v < 0$ .

Figure 6: Comparative statics effect of an increase in  $\epsilon$  on the demand for technological services.

Our simulations also confirm that as in Numerical Result 1, gross welfare:  $GW(\mu) = \mu(CE^{FD} - CE_1^{SD}) + CE_1^{SD} + \epsilon CE_2^{SD} + CE_1^L + CE_2^L$ , is increasing in  $\mu$ . Furthermore, we also find that  $GW(\mu)$  is increasing in  $\epsilon$ .

We can now use the model to rank market outcomes against the different welfare benchmarks introduced in Section 5:

**Numerical Result 5.** *With committed dealers ( $\epsilon = 0.05$ ), the results of our numerical simulations are as follows:*

1. *With high payoff volatility ( $\tau_v = 3$ ),  $\pi^M(\mu^{FB}) < 0$ , and the general ranking result of Proposition 8 applies.*
2. *With low payoff volatility ( $\tau_v = 25$ ), the monopoly profit function is larger and flatter than with  $\epsilon = 0$ . We have that  $\pi^M(\mu^{FB}) > 0$ , and:*

(a)  $\mu^{ST} = \mu^{UST}$ , and  $\mu^{CO} > \mu^{CFE} \geq \max\{\mu^{FB}, \mu^{ST}\}$ .

(b) *Entry regulation can yield a higher welfare than fee regulation when fixed costs are small.*

Furthermore, at all solutions  $N$  and  $\mu$  are decreasing in  $f$ .

Figure 7: The effect of committed dealers on  $\mu^{FD}$  (panel (a), left), the number of platforms (panel (a), right), and the welfare of market participants (panel (b)).

In Figure 7 we present a case in which, for a small entry cost, entry regulation yields a higher welfare than fee regulation, a result that is at odds with Proposition 8. The reason for this finding is as follows. The presence of committed dealers boosts the demand for technological services, making the monopoly solution “closer” to the First Best (with  $\epsilon > 0$ ,  $\pi^M(\mu^{FB})$  can be positive). In this case, increasing welfare via fee regulation, requires the planner to set  $\mu$  very high (much higher than at FB), substantially depressing industry profits for mild liquidity gains. Thus, for a small entry cost, controlling  $\mu$  by choosing  $N$  can be better. Summarizing:

- When  $\mu^M$  and  $\mu^{FB}$  are far apart ( $\pi^M(\mu^{FB}) < 0$ ), a very high  $N$  is needed to increase capacity via entry, which is very expensive in terms of fixed costs (see Figure 8, panel (a)), and it is optimal to control  $|mu$  to induce  $N = 1$ .
- When  $\mu^M$  and  $\mu^{FB}$  are closer ( $\pi^M(\mu^{FB}) > 0$ ), increasing welfare with CO substantially depresses industry profits for mild liquidity gains. In this case, it may be better to control  $\mu$  by choosing  $N$  (see Figure 8, panel (b)).

Figure 8: The figure illustrates the effectiveness of alternative regulatory tools to approach  $\mu^{FB}$ . In panel (a)  $\epsilon = 0$ ,  $\pi^M(\mu^{FB}) < 0$ , and fee regulation dominates. In panel (b)  $\epsilon > 0$ , and entry regulation can dominate.

## 6 Concluding remarks

We provide a model where competition among exchanges fosters innovation, benefiting traders. In the model, both supply and demand for liquidity arise endogenously, with the former depending on exchange competition. Exchanges compete in the provision of technological services which improve the participation of (full) dealers and allow them to absorb more of the net order flow, enhancing the risk bearing capacity of the market. At equilibrium, the mass of full dealers matches the industry technological service capacity. As a consequence, as exchange competition heightens, the mass of full dealers increases, improving market liquidity and traders' welfare. We use the model to analyze the welfare effects of different entry regimes. A monopolistic exchange exploits its market power, and under-supplies technological services, thereby negatively affecting liquidity and welfare. Allowing competition among trading platforms is beneficial for market quality and (generally) for welfare. However, the market outcome can overprovide or underprovide technological capacity with the corresponding effects on liquidity. If the regulator cannot make transfers to platforms, then entry is never insufficient and the market never underprovides capacity when the benchmark is regulated entry. If, on the other hand, side payments are possible, depending on parameter values entry can also be insufficient.

The optimal second best regulatory approach turns out to depend on the magnitude of the wedge between the technological capacity produced by a monopolistic exchange and the one a First Best planner would implement. When such a wedge is large, approaching the first best by spurring entry involves high total fixed costs. In this case, then, the planner limits market power by setting a fee low enough so that only one platform can break even and provide a larger (and cheaper) capacity than the market outcome. When, on the other hand, the wedge is small, the incremental welfare gain achieved through fee regulation is small compared to the industry profit depression this generates. In this case, the planner may find it better to control industry capacity by spurring entry. Both fee and entry regulation are subject to high informational requirements and to lobbying efforts. The choice between them has to weigh the respective costs and benefits.

Our results suggest that exchanges' technological capacity decisions can be an important *driver* of market liquidity, adding to the usual, demand-based factors highlighted by the market microstructure literature (e.g., arbitrage capital, risk bearing capacity of the market). Thus, any argument about market liquidity should be an-

chored to (i) the framework in which exchanges interact, and (ii) the type of regulatory intervention. Furthermore, we show the limits of the view aligning liquidity to welfare: with excessive entry, even though the market is more liquid, a social planner chooses to restrict competition, in this way reducing market liquidity.

Our modelling has integrated industrial organization and market microstructure methods taking technological services as homogeneous. An extension of our approach is to consider that exchanges offer differentiated capacities and introduce asymmetries among exchanges. Differentiation could be both in terms of quality (e.g., speed of connection) and horizontal attributes (e.g., lit vs. dark venues).<sup>38</sup>

---

<sup>38</sup>This would also allow to more directly contrast our results with the differentiated approach of Pagnotta and Philippon (2018).

## A Appendix

The following is a standard result (see, e.g., Vives (2008), Technical Appendix, pp. 382–383) that allows us to compute the unconditional expected utility of market participants.

**Lemma A.1.** *Let the  $n$ -dimensional random vector  $z \sim N(0, \Sigma)$ , and  $w = c + b'z + z'Az$ , where  $c \in \mathbb{R}$ ,  $b \in \mathbb{R}^n$ , and  $A$  is a  $n \times n$  matrix. If the matrix  $\Sigma^{-1} + 2\rho A$  is positive definite, and  $\rho > 0$ , then*

$$E[-\exp\{-\rho w\}] = -|\Sigma|^{-1/2}|\Sigma^{-1} + 2\rho A|^{-1/2} \exp\{-\rho(c - \rho b'(\Sigma^{-1} + 2\rho A)^{-1}b)\}.$$

### *Proof of Proposition 1*

We start by assuming that at a linear equilibrium prices are given by

$$p_2 = -\Lambda_2 u_2 + \Lambda_{21} u_1 \tag{A.1a}$$

$$p_1 = -\Lambda_1 u_1, \tag{A.1b}$$

with  $\Lambda_1$ ,  $\Lambda_{21}$ , and  $\Lambda_2$  to be determined in equilibrium. In the second period a new mass of liquidity traders with risk-tolerance coefficient  $\gamma^L > 0$  enter the market. Because of CARA and normality, the objective function of a second period liquidity trader is given by

$$E[-\exp\{-\pi_2^L/\gamma^L\}|\Omega_2^L] = -\exp\left\{-\frac{1}{\gamma^L}\left(E[\pi_2^L|\Omega_2^L] - \frac{1}{2\gamma^L}\text{Var}[\pi_2^L|\Omega_2^L]\right)\right\}, \tag{A.2}$$

where  $\Omega_2^L = \{u_1, u_2\}$ , and  $\pi_2^L \equiv (v - p_2)x_2^L + u_2v$ . Maximizing (A.2) with respect to  $x_2^L$ , yields:

$$X_2^L(u_1, u_2) = \gamma^L \frac{E[v - p_2|\Omega_2^L]}{\text{Var}[v - p_2|\Omega_2^L]} - \frac{\text{Cov}[v - p_2, v|\Omega_2^L]}{\text{Var}[v - p_2|\Omega_2^L]} u_2. \tag{A.3}$$

Using (A.1a):

$$E[v - p_2|\Omega_2^L] = \Lambda_2 u_2 - \Lambda_{21} u_1 \tag{A.4a}$$

$$\text{Var}[v - p_2|\Omega_2^L] = \text{Cov}[v - p_2, v|\Omega_2^L] = \frac{1}{\tau_v}. \tag{A.4b}$$

Substituting (A.4a) and (A.4b) in (A.3) yields

$$X_2^L(u_1, u_2) = a_2 u_2 + b u_1, \quad (\text{A.5})$$

where

$$a_2 = \gamma^L \tau_v \Lambda_2 - 1 \quad (\text{A.6a})$$

$$b = -\gamma^L \tau_v \Lambda_{21}. \quad (\text{A.6b})$$

Consider the sequence of market clearing equations

$$\mu x_1^{FD} + (1 - \mu)x_1^{SD} + x_1^L = 0 \quad (\text{A.7a})$$

$$\mu(x_2^{FD} - x_1^{FD}) + x_2^L = 0. \quad (\text{A.7b})$$

Condition (A.7b) highlights the fact that since first period liquidity traders and SD only participate at the first trading round, their positions do not change across dates. Rearrange (A.7a) as follows:

$$(1 - \mu)x_1^{SD} + x_1^L = -\mu x_1^{FD}.$$

Substitute the latter in (A.7b):

$$\mu x_2^{FD} + x_2^L + (1 - \mu)x_1^{SD} + x_1^L = 0. \quad (\text{A.8})$$

To pin down  $p_2$ , we need the second period strategy of FD and the first period strategies of SD and liquidity traders. Starting from the former, because of CARA and normality, the expected utility of a FD is given by:

$$\begin{aligned} E \left[ -\exp \left\{ -\frac{1}{\gamma} \left( (p_2 - p_1)x_1^{FD} + (v - p_2)x_2^{FD} \right) \right\} \middle| p_1, p_2 \right] &= \\ = \exp \left\{ -\frac{1}{\gamma} (p_2 - p_1)x_1^{FD} \right\} \left( -\exp \left\{ -\frac{1}{\gamma} \left( E[v - p_2 | p_1, p_2] x_2^{FD} - \frac{(x_2^{FD})^2}{2\gamma} \text{Var}[v - p_2 | p_1, p_2] \right) \right\} \right) & \end{aligned} \quad (\text{A.9})$$

For given  $x_1^{FD}$  the above is a concave function of  $x_2^{FD}$ . Maximizing with respect to  $x_2^{FD}$  yields:

$$X_2^{FD}(p_1, p_2) = -\gamma \tau_v p_2. \quad (\text{A.10})$$

Similarly, due to CARA and normality, in the first period a traditional market maker

maximizes

$$E \left[ -\exp \left\{ -\frac{1}{\gamma}(v - p_1)x_1^{SD} \right\} \middle| p_1 \right] = \quad (\text{A.11})$$

$$-\exp \left\{ -\frac{1}{\gamma} \left( E[v - p_1 | p_1] x_1^{SD} - \frac{(x_1^{SD})^2}{2\gamma} \text{Var}[v - p_1 | p_1] \right) \right\}.$$

Hence, his strategy is given by

$$X_1^{SD}(p_1) = -\gamma\tau_v p_1. \quad (\text{A.12})$$

Finally, consider a first period liquidity trader. CARA and normality imply

$$E[-\exp\{-\pi_1^L/\gamma^L\}] = -\exp \left\{ -\frac{1}{\gamma} \left( E[\pi_1^L | u_1] - \frac{1}{2\gamma^L} \text{Var}[\pi_1^L | u_1] \right) \right\}, \quad (\text{A.13})$$

where  $\pi_1^L \equiv (v - p_1)x_1^L + u_1v$ . Maximizing (A.13) with respect to  $x_1^L$ , and solving for the optimal strategy, yields

$$X_1^L(u_1) = \gamma^L \frac{E[v - p_1 | u_1]}{\text{Var}[v - p_1 | u_1]} - \frac{\text{Cov}[v - p_1, v | u_1]}{\text{Var}[v - p_1 | u_1]} u_1. \quad (\text{A.14})$$

Using (A.1b):

$$E[v - p_1 | u_1] = \Lambda_1 u_1 \quad (\text{A.15a})$$

$$\text{Cov}[v - p_1, v | u_1] = \frac{1}{\tau_v}. \quad (\text{A.15b})$$

Substituting the above in (A.14) yields

$$X_1^L(u_1) = a_1 u_1, \quad (\text{A.16})$$

where

$$a_1 = \gamma^L \tau_v \Lambda_1 - 1. \quad (\text{A.17})$$

Substituting (A.5), (A.10), (A.12), and (A.16) in (A.8) and solving for  $p_2$  yields

$$p_2 = -\underbrace{\frac{1 - \gamma^L \tau_v \Lambda_2}{\mu \gamma \tau_v}}_{\Lambda_2} u_2 + \underbrace{\frac{((1 - \mu)\gamma + \gamma^L)\tau_v \Lambda_1 - 1 - \gamma^L \tau_v \Lambda_{21}}{\mu \gamma \tau_v}}_{\Lambda_{21}} u_1. \quad (\text{A.18})$$

Identifying the price coefficients:

$$\Lambda_2 = \frac{1}{(\mu\gamma + \gamma^L)\tau_v} \quad (\text{A.19a})$$

$$\Lambda_{21} = \Lambda_2 \left( ((1 - \mu)\gamma + \gamma^L)\tau_v\Lambda_1 - 1 \right). \quad (\text{A.19b})$$

Substituting the above expressions in (A.18), and using (A.12) yields:

$$p_2 = -\Lambda_2 u_2 + \Lambda_2 \left( (1 - \mu)x_1^{SD} + x_1^L \right).$$

Consider now the first period. We start by characterizing the strategy of a FD. Substituting (A.10) in (A.9), rearranging, and applying Lemma A.1 yields the following expression for the first period objective function of a FD:

$$E[U((p_2 - p_1)x_1^{FD} + (v - p_2)x_2^{FD})|u_1] = - \left( 1 + \frac{\text{Var}[p_2|u_1]}{\text{Var}[v]} \right)^{-1/2} \times \quad (\text{A.20})$$

$$\exp \left\{ -\frac{1}{\gamma} \left( \frac{\gamma\tau_v}{2}\nu^2 + (\nu - p_1)x_1^{FD} - \frac{(x_1^{FD} + \gamma\tau_v\nu)^2}{2\gamma} \left( \frac{1}{\text{Var}[p_2|u_1]} + \frac{1}{\text{Var}[v]} \right)^{-1} \right) \right\},$$

where, due to (A.1a) and (A.1b)

$$\nu \equiv E[p_2|u_1] = \Lambda_{21}u_1 \quad (\text{A.21a})$$

$$\text{Var}[p_2|u_1] = \frac{\Lambda_2^2}{\tau_u}. \quad (\text{A.21b})$$

Maximizing (A.20) with respect to  $x_1^{FD}$  and solving for the first period strategy yields

$$X_1^{FD}(p_1) = \gamma \frac{E[p_2|u_1]}{\text{Var}[p_2|u_1]} - \gamma \left( \frac{1}{\text{Var}[p_2|u_1]} + \frac{1}{\text{Var}[v]} \right) p_1 \quad (\text{A.22})$$

$$= \gamma \frac{\Lambda_{21}\tau_u}{\Lambda_2^2} u_1 - \gamma \frac{\tau_u + \Lambda_2^2\tau_v}{\Lambda_2^2} p_1.$$

Substituting (A.12), (A.16), and (A.22) in (A.7a) and solving for the price yields  $p_1 = -\Lambda_1 u_1$ , where

$$\Lambda_1 = \left( \left( 1 + \frac{\mu\gamma^L\tau_u}{\Lambda_2 + \mu\gamma\tau_u} \right) \gamma + \gamma^L \right)^{-1} \frac{1}{\tau_v}. \quad (\text{A.23})$$

The remaining equilibrium coefficients are as follows:

$$a_1 = \gamma^L \Lambda_1 \tau_v - 1 \quad (\text{A.24})$$

$$a_2 = -\frac{\mu\gamma}{\mu\gamma + \gamma^L} \quad (\text{A.25})$$

$$b = -\gamma^L \tau_v \Lambda_{21} \quad (\text{A.26})$$

$$\Lambda_{21} = -\frac{\mu\gamma(\Lambda_2^2 \tau_v + \tau_u)}{\mu\gamma\tau_u + \Lambda_2} \Lambda_1 \quad (\text{A.27})$$

$$\text{Var}[p_2|u_1] = \frac{\Lambda_2^2}{\tau_u}, \quad (\text{A.28})$$

where  $\Lambda_2$  is given by (A.19a). An explicit expression for  $\Lambda_1$  can be obtained substituting (A.19a) into (A.23):

$$\Lambda_1 = \frac{1 + (\mu\gamma + \gamma^L)\mu\gamma\tau_u\tau_v}{(\gamma + \gamma^L + (\gamma + 2\gamma^L)(\mu\gamma + \gamma^L)\mu\gamma\tau_u\tau_v)\tau_v}. \quad (\text{A.29})$$

Finally, substituting (A.19a) and (A.29) in (A.27) yields

$$\Lambda_{21} + \Lambda_1 = \frac{\gamma^L}{\tau_v(\gamma\mu + \gamma^L)(\gamma\mu\tau_u\tau_v(\gamma + 2\gamma^L)(\gamma\mu + \gamma^L) + \gamma + \gamma^L)} > 0. \quad (\text{A.30})$$

□

### *Proof of Corollary 1*

The comparative static effect of  $\mu$  and  $\gamma$  on  $\Lambda_2$  follows immediately from (A.19a). For  $\Lambda_1$ , differentiating (A.29) with respect to  $\mu$  and  $\gamma$  yields:

$$\begin{aligned} \frac{\partial \Lambda_1}{\partial \mu} &= -\frac{(2\mu\gamma + \gamma^L)\gamma\gamma^L\tau_u}{(\gamma + \gamma^L + (\gamma + 2\gamma^L)(\mu\gamma + \gamma^L)\mu\gamma\tau_u\tau_v)^2} < 0 \\ \frac{\partial \Lambda_1}{\partial \gamma} &= -\frac{1 + (\gamma^2\mu\tau_u\tau_v(\gamma\mu + \gamma^L)^2 + 2\gamma^2\mu + 2\gamma\gamma^L\mu + 2\gamma\gamma^L + (\gamma^L)^2)\mu\tau_u\tau_v}{\tau_v(\gamma\mu\tau_u\tau_v(\gamma + 2\gamma^L)(\gamma\mu + \gamma^L) + \gamma + \gamma^L)^2} < 0, \end{aligned}$$

which proves our result. □

### *Proof of Corollary 2*

The first part of the corollary follows from the fact that  $\Lambda_1 < \Lambda_2$ . Also, since  $\Lambda_t$  is decreasing in  $\mu$ , because of (3d),  $|a_t|$  is increasing in  $\mu$ . Finally, substituting (A.27)

in (A.26) and rearranging yields

$$b = \frac{\mu\gamma\gamma^L(1 + (\mu\gamma + \gamma^L)^2\tau_u\tau_v)}{(\mu\gamma + \gamma^L)(\gamma + \gamma^L + (\gamma + 2\gamma^L)\mu\gamma\tau_u\tau_v)},$$

which is increasing in  $\mu$ . □

### *Proof of Proposition 2*

We start by obtaining an expression for the unconditional expected utility of SD and FD. Because of CARA and normality, a dealer's conditional expected utility evaluated at the optimal strategy is given by

$$\begin{aligned} E[U((v - p_1)x_1^{SD})|p_1] &= -\exp\left\{-\frac{(E[v|p_1] - p_1)^2}{2\text{Var}[v]}\right\} \\ &= -\exp\left\{-\frac{\tau_v\Lambda_1^2}{2}u_1^2\right\}. \end{aligned} \quad (\text{A.31})$$

Thus, traditional dealers derive utility from the expected, long term capital gain obtained supplying liquidity to first period hedgers.

$$\begin{aligned} EU^{SD} &\equiv E[U((v - p_1)x_1^{SD})] = -\left(1 + \frac{\text{Var}[p_1]}{\text{Var}[v]}\right)^{-1/2} \\ &= -\left(\frac{\tau_{u_1}}{\tau_{u_1} + \tau_v\Lambda_1^2}\right)^{1/2}, \end{aligned} \quad (\text{A.32})$$

and

$$CE^{SD} = \frac{\gamma}{2} \ln\left(1 + \frac{\text{Var}[p_1]}{\text{Var}[v]}\right). \quad (\text{A.33})$$

Differentiating  $CE^{SD}$  with respect to  $\mu$  yields:

$$\begin{aligned} \frac{\partial CE^{SD}}{\partial \mu} &= \frac{\gamma\tau_v}{2} \left(1 + \frac{\text{Var}[p_1]}{\text{Var}[v]}\right)^{-1} \frac{\partial \text{Var}[p_1]}{\partial \mu} \\ &= \frac{\gamma\tau_v}{2\tau_{u_1}} \left(1 + \frac{\text{Var}[p_1]}{\text{Var}[v]}\right)^{-1} 2\Lambda_1 \frac{\partial \Lambda_1}{\partial \mu} < 0, \end{aligned} \quad (\text{A.34})$$

since  $\Lambda_1$  is decreasing in  $\mu$ .

Turning to FD. Replacing (A.22) in (A.20) and rearranging yields

$$E[U((p_2 - p_1)x_1^{FD} + (v - p_2)x_2^{FD})|u_1] = - \left(1 + \frac{\text{Var}[p_2|u_1]}{\text{Var}[v]}\right)^{-1/2} \times \exp\left\{-\frac{g(u_1)}{\gamma}\right\}, \quad (\text{A.35})$$

where

$$g(u_1) = \frac{\gamma}{2} \left( \frac{(E[p_2|p_1] - p_1)^2}{\text{Var}[p_2|p_1]} + \frac{(E[v|p_1] - p_1)^2}{\text{Var}[v]} \right).$$

The argument at the exponential of (A.35) is a quadratic form of the first period endowment shock. We can therefore apply Lemma A.1 and obtain

$$\begin{aligned} EU^{FD} &\equiv E[U((p_2 - p_1)x_1^{FD} + (v - p_2)x_2^{FD})] = \\ &= - \left(1 + \frac{\text{Var}[p_2|p_1]}{\text{Var}[v]}\right)^{-1/2} \left(1 + \frac{\text{Var}[p_1]}{\text{Var}[v]} + \frac{\text{Var}[E[p_2|p_1] - p_1]}{\text{Var}[p_2|p_1]}\right)^{-1/2}, \end{aligned} \quad (\text{A.36})$$

where, because of (A.21a),

$$\text{Var}[E[p_2 - p_1|p_1]] = (\Lambda_{21} + \Lambda_1)^2 \tau_u^{-1}, \quad (\text{A.37})$$

so that:

$$\frac{\text{Var}[E[p_2 - p_1|u_1]]}{\text{Var}[p_2|u_1]} = \left(\frac{\Lambda_{21} + \Lambda_1}{\Lambda_2}\right)^2.$$

Therefore, we obtain

$$CE^{FD} = \frac{\gamma}{2} \left\{ \ln \left(1 + \frac{(\Lambda_2)^2 \tau_v}{\tau_u}\right) + \ln \left(1 + \frac{(\Lambda_1)^2 \tau_v}{\tau_u} + \left(\frac{\Lambda_{21} + \Lambda_1}{\Lambda_2}\right)^2\right) \right\}. \quad (\text{A.38})$$

Computing,

$$\frac{\Lambda_{21} + \Lambda_1}{\Lambda_2} = \frac{\gamma^L}{\gamma + \gamma^L + (\gamma + 2\gamma^L)(\mu\gamma + \gamma^L)\mu\gamma\tau_u\tau_v}. \quad (\text{A.39})$$

Thus, the arguments of the logarithms in (A.38) are decreasing in  $\mu$ , which proves that  $CE^{FD}$  is decreasing in  $\mu$ .

Finally, note that taking the limits for  $\mu \rightarrow 0$  and  $\mu \rightarrow 1$  in (A.33) and (A.38)

yields

$$\lim_{\mu \rightarrow 0} CE^{SD} = \frac{\gamma}{2} \ln \left( 1 + \frac{1}{(\gamma + \gamma^L)^2 \tau_u \tau_v} \right)$$

$$\lim_{\mu \rightarrow 1} CE^{FD} = \frac{\gamma}{2} \left\{ \ln \left( 1 + \frac{1}{(\gamma + \gamma^L)^2 \tau_u \tau_v} \right) + \ln \left( 1 + \frac{(\Lambda_1)^2 \tau_v}{\tau_u} + \left( \frac{\Lambda_{21} + \Lambda_1}{\Lambda_2} \right)^2 \right) \right\},$$

which proves the last part of the corollary.  $\square$

### *Proof of Proposition 3*

Consider now first period liquidity traders. Evaluating the objective function at optimum and rearranging yields

$$-\exp \left\{ -\frac{1}{\gamma^L} \left( E[\pi_1^L | u_1] - \frac{1}{2\gamma^L} \text{Var}[\pi_1^L | u_1] \right) \right\} = -\exp \left\{ -\frac{u_1^2}{\gamma^L} \left( \frac{a_1^2 - 1}{2\gamma^L \tau_v} \right) \right\},$$

where  $u_1 \sim N(0, \tau_{u_1}^{-1})$ . The argument at the exponential is a quadratic form of a normal random variable. Therefore, applying again Lemma A.1 yields

$$E \left[ -\exp \left\{ \frac{\pi_1^L}{\gamma^L} \right\} \right] = - \left( \frac{(\gamma^L)^2 \tau_u \tau_v}{(\gamma^L)^2 \tau_u \tau_v - 1 + a_1^2} \right)^{1/2}, \quad (\text{A.40})$$

so that

$$CE_1^L = \frac{\gamma^L}{2} \ln \left( 1 + \frac{a_1^2 - 1}{(\gamma^L)^2 \tau_u \tau_v} \right). \quad (\text{A.41})$$

Note that a higher  $a_1^2$  increases traders' expected utility, and thus increases their payoff.

Next, for second period liquidity traders, substituting the optimal strategy (A.3) in the objective function (A.2) yields

$$E \left[ -\exp \left\{ -\frac{\pi_2^L}{\gamma^L} \right\} | \Omega_2^L \right] = -\exp \left\{ -\frac{1}{\gamma^L} \left( \frac{(x_2^L)^2 - u_2^2}{2\gamma^L \tau_v} \right) \right\} \quad (\text{A.42})$$

$$= -\exp \left\{ -\frac{1}{\gamma^L} \begin{pmatrix} x_2^L & u_2 \end{pmatrix} \left( \frac{1}{2\gamma_2^L \tau_v} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \right) \begin{pmatrix} x_2^L \\ u_2 \end{pmatrix} \right\}.$$

The argument of the exponential is a quadratic form of the normally distributed random vector

$$\begin{pmatrix} x_2^L & u_2 \end{pmatrix} \sim N \left( \begin{pmatrix} 0 & 0 \end{pmatrix}, \Sigma \right),$$

where

$$\Sigma \equiv \begin{pmatrix} \text{Var}[x_2^L] & a_2 \text{Var}[u_2] \\ a_2 \text{Var}[u_2] & \text{Var}[u_2] \end{pmatrix}. \quad (\text{A.43})$$

Therefore, we can again apply Lemma A.1 to (A.42), obtaining

$$E \left[ E \left[ -\exp \left\{ -\frac{\pi_2^L}{\gamma^L} \right\} \middle| \Omega_2^L \right] \right] = -|I + (2/\gamma^L)\Sigma A|^{-1/2}, \quad (\text{A.44})$$

where

$$A \equiv \frac{1}{2\gamma^L\tau_v} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad (\text{A.45})$$

$$\text{Var}[x_2^L] = \frac{a_2^2 + b^2}{\tau_u}. \quad (\text{A.46})$$

Substituting (A.43), (A.45), and (A.46) in (A.44) and computing the certainty equivalent, yields:

$$CE_2^L = \frac{\gamma^L}{2} \ln \left( 1 + \frac{a_2^2 - 1}{(\gamma^L)^2\tau_u\tau_v} + \frac{b^2((\gamma^L)^2\tau_u\tau_v - 1)}{(\gamma^L)^4\tau_u^2\tau_v^2} \right). \quad (\text{A.47})$$

For  $\mu = 0$ ,  $b = 0$  and, in view of Corollary 2,  $CE_1^L > CE_2^L$ . The same condition holds when evaluating (A.41) and (A.47) at  $\mu = 1$ . As  $CE_t^L$  is increasing in  $\mu$ , we have that for all  $\mu \in (0, 1]$ ,  $CE_1^L(\mu) > CE_2^L(\mu)$ .  $\square$

### *Proof of Corollary 3*

We need to prove that:

$$\frac{\partial CE_1^L(\mu)}{\partial \mu} > -\frac{\partial CE^{SD}(\mu)}{\partial \mu}.$$

Computing:

$$\frac{\partial CE_1^L(\mu)}{\partial \mu} = \frac{\gamma^L a_1 a_1'}{(\gamma^L)^2 \tau_u \tau_v - 1 + a_1^2}, \quad (\text{A.48})$$

where  $a_1'$  the partial derivative of  $a_1$  with respect to  $\mu$ , and

$$\frac{\partial CE^{SD}(\mu)}{\partial \mu} = \frac{\gamma(1 + a_1)a_1'}{(\gamma^L)^2 \tau_u \tau_v + (1 + a_1)^2}. \quad (\text{A.49})$$

First, note that the denominator in (A.49) is higher than the one in (A.48), and they

are both positive. Next, comparing the numerators in the above expressions yields:

$$\gamma^L a_1 a'_1 > -\gamma(1 + a_1) a'_1 \iff \underbrace{(\gamma^L a_1 + \gamma(1 + a_1))}_{<0} \underbrace{a'_1}_{<0} > 0,$$

as can be checked by substituting (A.24) in the above. Thus, the LHS of the inequality to be proved has a higher (positive) numerator and a lower (positive) denominator compared to the (positive) numerator and denominator of the RHS, and the inequality follows.  $\square$

#### *Proof of Corollary 4*

The first part of the result follows immediately from (12), and Corollary 3. Next, because of Propositions 2 and 3,  $GW(1) > \lim_{\mu \rightarrow 0} GW(\mu)$ , which rules out the possibility that gross welfare is maximized at  $\mu \approx 0$ .  $\square$

#### *Proof of Corollary 5*

Note that because of (A.39), we can write

$$\frac{\Lambda_{21} + \Lambda_1}{\Lambda_2} = \frac{\Lambda_1 \gamma^L \tau_v}{1 + \mu \gamma (\mu \gamma + \gamma^L) \tau_u \tau_v}.$$

Therefore, substituting the expressions for dealers' payoffs in (13), we have:

$$\begin{aligned} \phi(\mu) &= CE^{FD} - CE^D & (A.50) \\ &= \frac{\gamma}{2} \left\{ \ln \left( 1 + \frac{\Lambda_2^2 \tau_v}{\tau_u} \right) + \ln \left( 1 + \frac{\Lambda_1^2 \tau_v}{\tau_u} K \right) - \ln \left( 1 + \frac{\Lambda_1^2 \tau_v}{\tau_u} \right) \right\} > 0. \end{aligned}$$

where  $K = 1 + (\gamma^L / (1 + \mu \gamma (\mu \gamma + \gamma^L) \tau_u \tau_v))^2 \tau_u \tau_v > 1$ , and decreasing in  $\mu$ . The first term inside curly braces in the above expression is decreasing in  $\mu$  since  $\Lambda_2$  is decreasing in  $\mu$ . The difference between the second and third terms can be written as follows:

$$\ln \left( 1 + \frac{\Lambda_1^2 \tau_v}{\tau_u} K \right) - \ln \left( 1 + \frac{\Lambda_1^2 \tau_v}{\tau_u} \right) = \ln \left( \frac{\tau_u + \Lambda_1^2 \tau_v K}{\tau_u + \Lambda_1^2 \tau_v} \right).$$

Differentiating the above logarithm and rearranging yields:

$$\frac{\tau_v \Lambda_1}{(\tau_u + \Lambda_1^2 \tau_v K)(\tau_u + \Lambda_1^2 \tau_v)} \left( 2(K - 1) \tau_u \frac{\partial \Lambda_1}{\partial \mu} + (\tau_u + \Lambda_1^2 \tau_u) \Lambda_1 \frac{\partial K}{\partial \mu} \right) < 0,$$

since  $K > 1$ , and both  $\Lambda_1$  and  $K$  are decreasing in  $\mu$ .  $\square$

We now state and prove a lemma which will be useful for some of the proofs that follow:

**Lemma A.2.**  $\pi^M(\mu^{FB}) \leq 0 \implies \pi^M(\mu^{CO}) = 0$ , and the converse is also true generically.

*Proof of Lemma A.2*

We first we prove the direction  $\implies$ . Since  $\pi^M(\mu^{FB}) \leq 0$  then, given that the monopoly profit is single-peaked, the CO constraints can only be satisfied for  $\mu \leq \mu^{FB}$ . Note that for a given (aggregate)  $\mu$ , the profit of an exchange (given that it is non-negative) is non-increasing in  $N$ ; so for a given  $\mu$ ,  $N = 1$  maximizes profit. Then, given that  $\mathcal{P}(\mu)$  is single-peaked at  $\mu^{FB}$ , it is optimal for  $\mu^{CO}$  to be set as large as possible with  $N^{CO} = 1$ , so that  $\pi^M(\mu^{CO}) = 0$ .

Next we prove the opposite direction ( $\impliedby$ ) generically by proving the contrapositive. Suppose that at  $\mu^{FB}$  the monopoly profit is positive, that is  $(\phi(\mu^{FB}) - c)\mu^{FB} > f$ , then:

1. If  $(\phi(\mu^{FB}) - c)\mu^{FB}/2 \leq f$ , then  $\mu^{CO} = \mu^{FB}$ ,  $N^{CO} = N^{FB} = 1$  and thus  $\pi^M(\mu^{CO}) > 0$ .
2. If  $(\phi(\mu^{FB}) - c)\mu^{FB}/2 > f$ , then given that from Proposition 5 we know that  $\mu^{CO} \geq \mu^M$ , and the monopoly profit is single peaked at  $\mu^M$  (thus, we work in the decreasing part of monopoly profit), we only need to examine whether it is optimal to choose  $N^{CO} > 1$  and/or  $\mu^{CO} > \mu^{FB}$  in order to satisfy the right CO constraint.

- (a) Assume that for  $N > 2$ , we do not have that  $(\phi(\mu^{FB}) - c)\mu^{FB}/N = f$ . We prove that it cannot be  $N^{CO} > 1$  with  $\mu^{CO} \leq \mu^{FB}$ . Suppose by contradiction that the latter holds. Then with  $\mu^{CO} = \mu^{FB}$ , the left CO constraint cannot bind and  $\pi^{CO}(\mu^{CO}) > 0$ . If  $\mu^{CO} < \mu^{FB}$ , then the left CO constraint must bind (and the right not):  $(\phi(\mu^{CO}) - c)\mu^{CO}/N^{CO} = f > (\phi(\mu^{CO}) - c)\mu^{CO}/(N^{CO} + 1)$ . (To see this, observe that if the left did not bind, we could increase  $\mu^{CO}$  to bring it closer to  $\mu^{FB}$  with both constraints still satisfied.) But then consider a new candidate CO solution resulting from reducing  $N^{CO}$  by one and increasing  $\mu^{CO}$  to  $\mu^{CO'} > \mu^{CO}$ .

From the previous left CO constraint we know that the new right CO constraint will not bind. Thus, it has to either be that  $\mu^{CO'} = \mu^{FB}$ , in which case  $(\mu^{CO}, N^{CO})$  is rejected as a solution and we have a contradiction, or that the new left CO constraint will bind—to see the latter, it suffices to observe that if neither constraint binds and  $\mu^{CO'} \neq \mu^{FB}$ , there is  $\epsilon > 0$  small enough such that either  $\mu^{CO'} + \epsilon$  or  $\mu^{CO'} - \epsilon$  increases the planner's function. In the case that the new left constraint binds, we have that  $(\phi(\mu^{CO'}) - c)\mu^{CO'}/(N^{CO} - 1) = f > (\phi(\mu^{CO'}) - c)\mu^{CO'}/(N^{CO})$ , so  $\mu^{CO'} < \mu^{FB}$  (consider a similar argument of reducing  $\mu^{CO'}$  by  $\epsilon$  to exclude  $\mu^{CO'} > \mu^{FB}$ ). This case also induces  $P(\mu^{CO'}, N^{CO} - 1) > P(\mu^{CO}, N^{CO})$ , as  $\mu^{CO} < \mu^{CO'} < \mu^{FB}$ . We conclude that it cannot be that  $N^{CO} > 1$  with some  $\mu^{CO} < \mu^{FB}$ .

- (b) Now consider the case  $N^{CO} \geq 1$  with  $\mu^{CO} > \mu^{FB}$ . Then the right CO constraint must bind (and the left not):  $(\phi(\mu^{CO}) - c)\mu^{CO}/N^{CO} > f = (\phi(\mu^{CO}) - c)\mu^{CO}/(N^{CO} + 1)$ . To see this, observe that if the right did not bind, we could reduce  $\mu^{CO}$  to bring it closer to  $\mu^{FB}$  with both constraints still satisfied. Thus,  $\pi^M(\mu^{CO}) = (\phi(\mu^{CO}) - c)\mu^{CO}/N^{CO} - f > 0$ .  $\square$

### *Proof of Proposition 5*

In the First Best case, for given  $\mu$ , the objective function (18) is decreasing in  $N$ . Thus, to economise on fixed costs, the planner allows a monopolistic exchange to provide trading services, and  $N^{FB} = 1$ . From  $\pi^M(\mu^{FB}) \leq 0$  it follows that:

$$(\phi(\mu^{FB}) - c)\mu^{FB} \leq f \implies \frac{(\phi(\mu^{FB}) - c)\mu^{FB}}{N} < f, \forall N \in \mathbb{N} \setminus \{1\}.$$

We now establish the technological capacity and liquidity ranking. First, note that it cannot be  $N^{CFE} = 1$  and  $\mu^{CFE} \geq \mu^{FB}$ . This is because for  $N^{CFE} = 1$ ,  $\mu^{CFE} = \mu^M$  and by assumption the monopolist makes positive profits. Thus, it will be  $\mu^{CFE} < \mu^{FB}$ . Finally, by Cournot stability,  $\mu^{CFE} \geq \mu^M$  (see also the proof of Proposition 7), with the final implication that  $\mu^{FB} > \mu^{CFE} \geq \mu^M$ .

We now prove the welfare ranking. Since  $\mu^{FB} > \mu^M$  and  $\mathcal{P}(\mu, 1)$  is single-peaked at  $\mu^{FB}$ , it follows that  $\mathcal{P}^{FB} > \mathcal{P}^M$ . Also, we have that  $\mathcal{P}(\mu, 1) = GW(\mu) - c\mu - f$  is

single-peaked in  $\mu$  at  $\mu^{FB}$ , which means that  $GW(\mu) - c\mu$  is also single-peaked. Thus, since  $\mu^{FB} > \mu^{CFE}$  we have:

$$\begin{aligned}\mathcal{P}^{FB} &= GW(\mu^{FB}) - c\mu^{FB} - f > GW(\mu^{CFE}) - c\mu^{CFE} - f \\ &\geq GW(\mu^{CFE}) - c\mu^{CFE} - fN^{CFE} = \mathcal{P}^{CFE}\end{aligned}$$

and so overall we have  $\mathcal{P}^{FB} > \max\{\mathcal{P}^{CFE}, \mathcal{P}^M\} \geq \min\{\mathcal{P}^{CFE}, \mathcal{P}^M\}$ .  $\square$

### *Proof of Proposition 6*

Given that the monopoly profit is negative at  $\mu^{FB}$  (so that it cannot be  $\mu^{FB} \leq \mu^{CO}$ ), it will be  $N^{CO} = 1$  and  $\mu^{FB} > \mu^{CO}$  so that profits are zero at the CO solution (look also at the proof of Lemma A.2).

We now prove that  $\mu^{CO} > \mu^{CFE}$ . Suppose, by contradiction, that  $\mu^{CFE} \geq \mu^{CO}$ . From  $\pi^M(\mu^{FB}) < 0$  we know that at the Conduct Second Best  $N^{CO} = 1$  and the exchange breaks even, so given that  $\psi'(\mu) > 0$  we have:

$$(\phi(\mu^{CFE}) - c)\mu^{CFE} \leq f. \quad (\text{A.51})$$

We first deal with the case where only one firm enters at CFE, and then with the one where  $N^{CFE} > 1$ . At a CFE with  $N = 1$  exchanges, we have  $\mu^{CFE} = \mu^M$  and thus the monopolist profit is positive by assumption:

$$(\phi(\mu^{CFE}) - c)\frac{\mu^{CFE}}{N} = (\phi(\mu^{CFE}) - c)\mu^{CFE} = (\phi(\mu^M) - c)\mu^M > f. \quad (\text{A.52})$$

Putting together (A.51) and (A.52) leads to a contradiction.

At a CFE with  $N > 1$  exchanges, we need to have:

$$(\phi(\mu^{CFE}) - c)\frac{\mu^{CFE}}{N} \geq f. \quad (\text{A.53})$$

Putting together (A.51) and (A.53) yields

$$f \leq (\phi(\mu^{CFE}) - c)\frac{\mu^{CFE}}{N} < (\phi(\mu^{CFE}) - c)\mu^{CFE} \leq f,$$

a contradiction. Thus, we must have  $\mu^{CO} > \mu^{CFE}$ .

Now, since  $N^{FB} = N^{CO} = 1 \leq N^{CFE}$ , it follows that  $\mathcal{P}^{FB} > \mathcal{P}^{CO} > \mathcal{P}^{CFE}$  since  $\mu^{FB} > \mu^{CO} > \mu^{CFE}$  and  $\mathcal{P}(\mu, 1)$  is single-peaked at  $\mu^{FB}$  and, all else constant,  $\mathcal{P}(\mu, N)$  is decreasing in  $N$ .  $\square$

*Proof of Proposition 7*

Let  $\mu^C(N)$  denote the total co-location capacity at a symmetric Cournot equilibrium for a given number of exchanges  $N$ . The objective function of a planner that controls entry can be written as follows:

$$\mathcal{P}(\mu^C(N), N) = N\pi_i(\mu^C(N)) + \psi(\mu^C(N)), \quad (\text{A.54})$$

where  $\psi(\mu^C(N))$  denotes the welfare of other market participants at the Cournot solution:

$$\psi(\mu^C(N)) = CE^{SD}(\mu^C(N)) + CE_1^L(\mu^C(N)) + CE_2^L(\mu^C(N)).$$

Consider now the derivative of the planner's objective function with respect to  $N$ , and evaluate it at  $N^{CFE}$ :

$$\begin{aligned} \left. \frac{\partial \mathcal{P}(\mu^C(N), N)}{\partial N} \right|_{N=N^{CFE}} &= \underbrace{\pi_i(\mu^C(N), N)}_{=0} \Big|_{N=N^{CFE}} \\ &+ N^{CFE} \underbrace{\frac{\partial \pi_i(\mu^C(N), N)}{\partial N}}_{<0} \Big|_{N=N^{CFE}} + \psi'(\mu^C(N)) \underbrace{\frac{\partial \mu^C(N)}{\partial N}}_{>0} \Big|_{N=N^{CFE}}. \end{aligned} \quad (\text{A.55})$$

The first term on the right hand side of (A.55) is null at  $N^{CFE}$  (modulo the integer constraint). At a stable, symmetric Cournot equilibrium, an increase in  $N$  has a negative impact on the profit of each exchange, and a positive impact on the aggregate technological capacity (see, e.g., Vives (1999)). Therefore, the second and third terms are respectively negative and positive. Given our definitions,  $N^{CFE}$  is the largest  $N$  such that platforms break even.  $N^{ST}$ , instead, reflects the planner's choice of  $N$  in Cournot equilibria that keep exchanges from making negative profits and maximizes welfare. Hence, it can only be that

$$N^{CFE} \geq N^{ST} \text{ and } \mu^{CFE} \geq \mu^{ST},$$

since a planner can decide to restrict entry. At a  $UST$ , the planner can make side payments to an unprofitable exchange. This has two implications: first, the planner can push entry beyond the level at which platforms break even, so that

$$N^{UST} \geq N^{ST} \text{ and } \mu^{UST} \geq \mu^{ST}.$$

Additionally, depending on which of the two terms in (A.55) prevails, we have

$$\left. \frac{\partial \mathcal{P}(\mu^C(N), N)}{\partial N} \right|_{N=N^{CFE}} \geq 0 \implies N^{CFE} \leq N^{UST}.$$

Finally,  $\mu^C(N) \geq \mu^M$ , for  $N \geq 1$  because at a stable CFE the total capacity is an increasing function of the number of platforms. A similar argument holds at both the STR and UST, since in this case the planner picks  $N$  subject to  $\mu$  being a Cournot equilibrium

We have that  $\mathcal{P}^{UST} \geq \mathcal{P}^{ST}$ , because STR imposes an additional constraint on the planner's objective function compared to STR. Finally,  $\mathcal{P}^{ST} \geq \mathcal{P}^{CFE}$ , because CFE does not account for other traders' welfare, and the planner may choose to favour these market participants when at the margin this creates a larger increase in  $GW(\mu)$ .  $\square$

### *Proof of Proposition 8*

From Propositions 6 and 7 we have  $N^{CO} = 1$ ,  $\mu^{FB} > \mu^{CO} > \mu^{CFE} \geq \mu^{ST}$ ,  $\mathcal{P}^{FB} > \mathcal{P}^{CO} > \mathcal{P}^M$ , and by Cournot stability  $\mu^{ST} \geq \mu^M$ . Also, we have that  $\mathcal{P}(\mu, 1) = GW(\mu) - c\mu - f$  is single-peaked in  $\mu$  at  $\mu^{FB}$ , which means that  $GW(\mu) - c\mu$  is so. Thus, since  $\mu^{CO} > \mu^{CFE} \geq \mu^{ST}$  we have:

$$\begin{aligned} \mathcal{P}^{CO} &= GW(\mu^{CO}) - c\mu^{CO} - f > GW(\mu^{ST}) - c\mu^{ST} - f \\ &\geq GW(\mu^{ST}) - c\mu^{ST} - fN^{ST} = \mathcal{P}^{ST} \end{aligned}$$

and so  $\mathcal{P}^{CO} > \mathcal{P}^{ST} \geq \mathcal{P}^{CFE}$ , where the weak inequality follows from the fact that the CFE solution is always available in solving the STR problem. For the same reason,  $\mathcal{P}^{FB} \geq \mathcal{P}^{UST} \geq \mathcal{P}^{ST} \geq \mathcal{P}^M$ . Thus, overall we have:

$$\mathcal{P}^{FB} > \mathcal{P}^{CO} > \mathcal{P}^{ST} \geq \max \{ \mathcal{P}^{CFE}, \mathcal{P}^M \} \geq \min \{ \mathcal{P}^{CFE}, \mathcal{P}^M \}.$$

Last, evaluate the derivative of welfare with respect to  $\mu$  at the  $UST$  solution:

$$\left. \frac{\partial \mathcal{P}(\mu, N)}{\partial \mu} \right|_{(\mu, N) = (\mu^{UST}, N^{UST})} = [\phi'(\mu)\mu + \phi(\mu) - c] \Big|_{\mu = \mu^{UST}}$$

The FOC of a firm  $i$  in  $UST$  reads:

$$\left[ \frac{\phi'(\mu)\mu}{N} + \phi(\mu) - c \right] \Big|_{(\mu, N) = (\mu^{UST}, N^{UST})} = 0.$$

Combining this with the above we have:

$$\left. \frac{\partial \mathcal{P}(\mu, N)}{\partial \mu} \right|_{(\mu, N) = (\mu^{UST}, N^{UST})} = \phi'(\mu)\mu \frac{N-1}{N} \Big|_{(\mu, N) = (\mu^{UST}, N^{UST})} < 0$$

so the  $UST$  solution does not maximize welfare given that the  $FB$  solution is interior (and thus, for the  $UST$  solution to maximize welfare the derivative above should have been zero), so it must be  $\mathcal{P}^{FB} > \mathcal{P}^{UST}$ .  $\square$

## B A model with SD at the second round

In this appendix we consider a variation of the model presented in Section 3, in which we assume that SD enter the market at the second round of the liquidity determination stage of the game (the proofs of the results involve minor variations from the ones in Appendix A, and are available upon request). This captures the intuition that through technological services FD are quicker in accommodating liquidity traders' demand shocks than SD. In this case, the market clearing conditions in periods 1 and 2 are given respectively by  $x_1^L + \mu x_1^{FD} = 0$  and  $x_2^L + \mu(x_2^{FD} - x_1^{FD}) + (1 - \mu)x_2^{SD} = 0$  (see Figure B.1 for the modified timeline). We restrict attention to linear equilibria where

$$p_1 = -\tilde{\Lambda}_1 u_1 \quad (\text{B.1a})$$

$$p_2 = -\tilde{\Lambda}_2 u_2 + \tilde{\Lambda}_{21} u_1, \quad (\text{B.1b})$$

where we use  $\sim$  to denote variables related to the model with SD entering at the second round.

Figure B.1: Timeline in the model where SD enter at the second round.

We obtain the following result:

**Proposition B.1.** *For  $\mu \in (0, 1]$ , there exists a unique equilibrium in linear strategies in the stock market where SD enter at the second round. Compared to the baseline case,  $\tilde{\Lambda}_1 > \Lambda_1$ ,  $\Lambda_1 < \tilde{\Lambda}_2 < \Lambda_2$ , and  $|\tilde{\Lambda}_{21}| > |\Lambda_{21}|$ .*

Thus, SD entry at the second round reduces (increases) the competitive pressure

faced by FD at the first (second) round, explaining the decrease (increase) in first (second) period liquidity. Comparing dealers' payoffs across the two models, we find

**Proposition B.2.**  $\widetilde{CE}^{FD} > \widetilde{CE}^{SD}$ , and SD have a higher payoff when entering in the second round, whereas the result for FD is ambiguous:  $\widetilde{CE}^{SD} > CE^{SD}$ , and  $\widetilde{CE}^{FD} \geq CE^{FD}$ .

As in the baseline model, more access to the liquidity supply market has value for dealers. In the baseline model, in the first round FD supply liquidity anticipating the possibility to rebalance their position at the second round. This heightens the competitive pressure they exert on SD compared to the model studied in this section, explaining why  $\widetilde{CE}^{SD} > CE^{SD}$ . Conversely, the payoff comparison for FD is less clear cut. Indeed, compared to the baseline model, liquidity is lower (higher) at the first (second) round. We define the demand for technological services as  $\tilde{\phi}(\mu) = \widetilde{CE}^{FD} - \widetilde{CE}^{SD}$ .

**Proposition B.3.** *In the model where SD enter at the second round,  $\tilde{\phi}(\mu)$  is decreasing in  $\mu$ .*

Furthermore, numerical simulations show that even in this case, the demand for technological services can be log-convex, implying that strategic complementarities in platform capacity decisions can arise.

## C A model with a mass of SD at both rounds

In this appendix, we consider a different variation of the model presented in Section 3, in which we assume that a mass  $\epsilon$  of “committed” SD is in the market at each trading round, and cannot choose to become FD—so that a total mass of  $2\epsilon$  SD is unable to become FD. As a consequence, at the first round liquidity is supplied by  $\mu$  FD, and a mass

$$\underbrace{\epsilon}_{\text{Committed SD}} + \underbrace{1 - \epsilon - \mu}_{\text{SD}} = 1 - \mu$$

of SD. At the second round, instead, we have a total mass  $\mu$  FD and  $\epsilon$  SD of liquidity suppliers (see Figure C.1 for the modified timeline of the model).

Figure C.1: Timeline in the model with committed SD.

In the following, we provide the proof for Proposition 9.

To obtain the equilibrium of the liquidity provision model in this case, we start by assuming that equilibrium prices are as follows:

$$p_1 = -\tilde{\Lambda}_1 u_1 \tag{C.1a}$$

$$p_2 = -\tilde{\Lambda}_2 u_2 + \tilde{\Lambda}_{21} u_1. \tag{C.1b}$$

where  $\tilde{\Lambda}_{21}$ ,  $\tilde{\Lambda}_t$ ,  $t \in \{1, 2\}$  denote the price coefficients to be determined at equilibrium.

The market clearing conditions are then given by:

$$\mu x_1^{FD} + (1 - \mu)x_1^{SD} + x_1^L = 0 \quad (\text{C.2a})$$

$$(x_2^{FD} - x_1^{FD})\mu + \epsilon x_2^{SD} + x_2^L = 0. \quad (\text{C.2b})$$

We now obtain the equilibrium strategies of market participants. For a second period liquidity trader, (A.5) holds:

$$x_2^L = \tilde{a}_2 u_2 + \tilde{b} u_1, \quad (\text{C.3})$$

where

$$\tilde{a}_2 = \gamma^L \tau_v \tilde{\Lambda}_2 - 1 \quad (\text{C.4a})$$

$$\tilde{b} = -\gamma^L \tau_v \tilde{\Lambda}_{21}, \quad (\text{C.4b})$$

denote the coefficient of a second period liquidity trader in the current version of the liquidity provision model. Based on the arguments developed in the proof of Proposition 1, for a SD who is in the market at round  $t$ , we have:

$$x_t^{SD} = -\gamma \tau_v p_t, \quad (\text{C.5})$$

whereas for a FD at the second round,

$$x_2^{FD} = -\gamma \tau_v p_2. \quad (\text{C.6})$$

For a first period liquidity trader (A.16) holds:

$$x_1^L = \tilde{a}_1 u_1 \quad (\text{C.7a})$$

$$\tilde{a}_1 = \gamma^L \tau_v \tilde{\Lambda}_1 - 1. \quad (\text{C.7b})$$

Finally, for a FD at the first trading round (A.22) holds.

Solving the first period market clearing condition (C.2a) for  $-x_1^{FD}$  and replacing it in the second period market clearing condition (C.2b) yields

$$\mu x_2^{FD} + (1 - \mu)x_1^{SD} + x_1^L + x_2^L + \epsilon x_2^{SD} = 0. \quad (\text{C.8})$$

We can now replace SD, FD and liquidity traders' strategies from (C.5), (C.6), (C.3), and (C.7a) in the market clearing condition (C.8), and identify the second period price

equilibrium coefficients:

$$p_2 = \underbrace{\frac{(1-\mu)\gamma\tau_v\tilde{\Lambda}_1 + \tilde{a}_1 + \tilde{b}}{(\epsilon + \mu)\gamma\tau_v}}_{\tilde{\Lambda}_{21}} u_1 + \underbrace{\frac{\tilde{a}_2}{(\epsilon + \mu)\gamma\tau_v}}_{\tilde{\Lambda}_2} u_2. \quad (\text{C.9})$$

Finally, using (C.4a), (C.4b), and (C.7b) in the expressions for  $\tilde{\Lambda}_2$  and  $\tilde{\Lambda}_{21}$  in (C.9), we identify the second period price coefficients, obtaining:

$$\tilde{\Lambda}_2 = \frac{1}{((\epsilon + \mu)\gamma + \gamma^L)\tau_v} \quad (\text{C.10a})$$

$$\tilde{\Lambda}_{21} = -(1 - ((1 - \mu)\gamma + \gamma^L)\tau_v\tilde{\Lambda}_1)\tilde{\Lambda}_2. \quad (\text{C.10b})$$

Therefore, the model with a fixed mass of SD at both rounds induces a lower  $\tilde{\Lambda}_2$ , as one would expect.

The analysis of the first round does not change compared to the baseline model, since in that case too a mass  $\mu$  of SD is in the market. To determine  $\tilde{\Lambda}_1$  we replace the strategies of liquidity providers (FD and SD), and liquidity traders in the first period market clearing equation (C.2a), solve for  $p_1$ , and identify  $\tilde{\Lambda}_1$  which, according to (A.23) is given by:

$$\tilde{\Lambda}_1 = \left( \left( 1 + \frac{\mu\gamma^L\tau_u}{\tilde{\Lambda}_2 + \mu\gamma\tau_u} \right) \gamma + \gamma^L \right)^{-1} \frac{1}{\tau_v}. \quad (\text{C.11})$$

We only need to keep in mind the change in  $\tilde{\Lambda}_2$ , which implies the following closed form expression for the first period price impact:

$$\tilde{\Lambda}_1 = \frac{1 + \gamma\mu\tau_u\tau_v(\gamma^L + \gamma(\mu + \epsilon))}{(\gamma + \gamma^L + \gamma\mu\tau_u\tau_v(\gamma + 2\gamma^L)(\gamma^L + \gamma(\mu + \epsilon)))\tau_v} > 0. \quad (\text{C.12})$$

Note that since  $\tilde{\Lambda}_2$  is decreasing in  $\epsilon$ , based on (C.12), and (C.10b) it follows that  $\tilde{\Lambda}_1$  is also decreasing in  $\epsilon$ , and differentiating  $\tilde{\Lambda}_{21}$ :

$$\begin{aligned} \frac{\partial \tilde{\Lambda}_{21}}{\partial \epsilon} &= \\ & \frac{\gamma^2\mu \left( (\gamma + \gamma^L)/\tau_v + \gamma\mu\tau_u^2\tau_v(\gamma + 2\gamma^L)(\gamma\mu + \gamma^L)(\gamma^L + \gamma(\mu + \epsilon))^2 + 2\gamma\mu\tau_u(\gamma + 2\gamma^L)(\gamma^L + \gamma(\mu + \epsilon)) \right)}{(\gamma^L + \gamma(\mu + \epsilon))^2(\gamma + \gamma^L + \gamma\mu\tau_u\tau_v(\gamma + 2\gamma^L)(\gamma^L + \gamma(\mu + \epsilon)))^2} \\ & > 0, \end{aligned}$$

implying that  $|\tilde{\Lambda}_{21}|$ , and  $\tilde{b}$  are decreasing in  $\epsilon$ .

Furthermore, since  $\tilde{\Lambda}_t$  is decreasing in  $\epsilon$ , due to (C.4a) and (C.7b),  $|\tilde{a}_t|$  is increasing in  $\epsilon$ , and since by inspection  $\tilde{\Lambda}_1 < \tilde{\Lambda}_2$ ,  $|\tilde{a}_1| > |\tilde{a}_2|$ , this concludes the proof of Proposition 9

Committed dealers improve the risk bearing capacity of the market, increasing its liquidity at both rounds, and leading traders to hedge a larger fraction of their endowment shock. As second period traders face heightened competition in speculating against the propagated endowment shock, a larger  $\epsilon$  reduces their response to  $u_1$  ( $\tilde{b}$ ).

Next, we compute the payoff functions for the different market participants which, based on the analysis of the baseline case explained in the paper, are given by:

$$CE_1^{SD} = \frac{\gamma}{2} \ln \left( 1 + \frac{\tilde{\Lambda}_1^2 \tau_v}{\tau_u} \right). \quad (\text{C.13a})$$

$$CE^{FD} = \frac{\gamma}{2} \left( \ln \left( 1 + \frac{\tilde{\Lambda}_1^2 \tau_v}{\tau_u} + \left( \frac{\tilde{\Lambda}_{21} + \tilde{\Lambda}_1}{\tilde{\Lambda}_2} \right)^2 \right) + \ln \left( 1 + \frac{\tilde{\Lambda}_2^2 \tau_v}{\tau_u} \right) \right), \quad (\text{C.13b})$$

where we note that, in view of Proposition 9,  $CE_1^{SD}$  is decreasing in  $\mu$ , and since

$$\frac{\partial}{\partial \mu} \frac{\tilde{\Lambda}_{21} + \tilde{\Lambda}_1}{\tilde{\Lambda}_2} = - \frac{\gamma \gamma^L \tau_u \tau_v (\gamma + 2\gamma^L + \gamma \epsilon) (2\gamma \mu + \gamma^L + \gamma \epsilon)}{(\gamma + \gamma^L + \gamma \mu \tau_u \tau_v (\gamma + 2\gamma^L) (\gamma^L + \gamma(\mu + \epsilon)))^2} < 0,$$

$CE^{FD}$  is also decreasing in  $\mu$ . Also, we have

$$CE_1^L = \frac{\gamma^L}{2} \ln \left( 1 + \frac{\text{Var}[E[v - p_1 | p_1]]}{\text{Var}[v - p_1 | p_1]} + 2 \frac{\text{Cov}[p_1, u_1]}{\gamma^L} \right) \quad (\text{C.14a})$$

$$CE_2^L = \frac{\gamma^L}{2} \ln \left( 1 + \frac{\text{Var}[E[v - p_2 | p_1, p_2]]}{\text{Var}[v - p_2 | p_1, p_2]} + 2 \frac{\text{Cov}[p_2, u_2 | p_1]}{\gamma^L} + \frac{\text{Var}[E[v - p_2 | p_1]]}{\text{Var}[v]} - \left( \frac{\text{Cov}[p_2, u_1]}{\gamma^L} \right)^2 \right), \quad (\text{C.14b})$$

and a substitution similar to the one made in the case  $\epsilon = 0$  allows to express traders' payoffs in terms of the equilibrium coefficients and conclude that they  $CE_t^L$  is increasing in  $\mu$ .

Finally, since the strategy of a second round SD, bar the time index, is identical to

that of a SD at the first round, we have:

$$CE_2^{SD} = \frac{\gamma}{2} \ln \left( 1 + \frac{\text{Var}[p_2|p_1]}{\text{Var}[v]} \right) = \frac{\gamma}{2} \ln \left( 1 + \frac{\tilde{\Lambda}_2^2 \tau_v}{\tau_u} \right), \quad (\text{C.15})$$

which, in view of Proposition 9, is decreasing in  $\mu$ .

Comparing (C.13b) with (C.13a) we see that  $CE^{FD} > CE_1^{SD}$ , and, consistently with what we have done in the baseline case, we define the demand for technological services as the difference between the payoff of a FD and the one of a first period SD:

$$\phi(\mu) = CE^{FD} - CE_1^{SD}.$$

Differentiating the above expression with respect to  $\mu$  yields  $\partial\phi/\partial\mu > 0$ . This and the above comparative statics results prove Corollary 7.

The above result confirms that an increase in the mass of FD is harmful (beneficial) to liquidity providers (consumers). We then define the gross welfare function:

$$\begin{aligned} G(\mu) &= \mu CE^{FD} + (1 - \mu) CE_1^{SD} + \epsilon CE_2^{SD} + CE_1^L + CE_2^L \\ &= \underbrace{\mu(CE^{FD} - CE_1^{SD})}_{\text{FD surplus}} + \underbrace{CE_1^{SD} + \epsilon CE_2^{SD} + CE_1^L + CE_2^L}_{\text{Welfare of other market participants}}, \end{aligned}$$

which, according to our simulations, is increasing in  $\mu$ .

Finally, we obtain the following additional comparative statics results for the effect of an increase in  $\epsilon$ :

1. Numerical simulations show that  $GW(\mu)$  is increasing in  $\epsilon$ .
2. Simulations also show that  $CE^{FD}$ ,  $CE_t^L$  and  $\phi(\mu)$  are increasing in  $\epsilon$ . The effect on FDs payoff comes from the term that captures the payoff these traders obtain from short-term speculation which, based on (C.13b), is given by

$$\frac{\tilde{\Lambda}_{21} + \tilde{\Lambda}_1}{\tilde{\Lambda}_2}.$$

This term is increasing in  $\epsilon$ :

$$\frac{\partial \tilde{\Lambda}_{21} + \tilde{\Lambda}_1}{\partial \epsilon \tilde{\Lambda}_2} = \frac{\gamma (\gamma + \gamma^L + \gamma^2 \mu^2 \tau_u^2 \tau_v^2 (\gamma + 2\gamma^L) (\gamma^L + \gamma(\mu + \epsilon))^2 + \gamma \mu \tau_u \tau_v (\gamma \mu (2\gamma + 3\gamma^L) + (\gamma + \gamma^L) (\gamma^L + 2\gamma \epsilon)))}{(\gamma + \gamma^L + \gamma \mu \tau_u \tau_v (\gamma + 2\gamma^L) (\gamma^L + \gamma(\mu + \epsilon)))^2} > 0,$$

while the remaining terms of FD payoff (based on the results of the liquidity provision model), are decreasing in  $\epsilon$ . Therefore, the positive effect of an additional mass of SD for FD comes from improved risk sharing opportunities. With a larger  $\epsilon$ , FD have more traders with whom to share the risk loaded at the first round. For liquidity traders, the effect is due the fact that they can get cheaper liquidity provision at both rounds (see (C.10a) and (C.12)).

3. Finally, owing to (C.13a), we have that  $CE_t^{SD}$  is decreasing in  $\epsilon$ .

Summarizing: qualitatively, in terms of impact on (1) liquidity, (2) market participants' payoffs and (3) gross welfare, the addition of a mass  $\epsilon$  of standard dealers who are always in the market does not affect our main results. However, as argued in the main text (see Numerical Result 5), as committed dealers augment the risk-bearing capacity of the market, they potentially increase the value of technological services, in this way affecting the planner's preferred second best intervention policy.

## D A permanent shock to dealers' risk tolerance

In this appendix we use our model to study the effect of a permanent shock to liquidity providers' risk tolerance. As is usual in a setup where dealers are risk averse, a lower  $\gamma$  reduces market liquidity (Corollary 1). However, liquidity also depends positively on the proportion of FD (Corollary 1), which is pinned down by the equilibrium arising at the technological capacity determination stage of the game. As a consequence in our setup an additional effect, working through the impact of a change in risk tolerance on the mass of FDs, impinges on market liquidity.

In the following, we first establish that the demand for technological services can be *decreasing* in  $\gamma$  (Corollary D.1). We then use this finding to show via numerical simulations, that a permanent decrease in the risk tolerance of liquidity providers can lead to an increase in liquidity.

**Corollary D.1.** *An increase in  $\gamma$  has two contrasting effects on the inverse demand for technological services  $\phi(\mu) = \gamma \ln(EU^{FD}/EU^{SD})^{1/2}$ :*

$$\frac{\partial \phi(\mu)}{\partial \gamma} = \underbrace{\frac{1}{2} \ln \left( \frac{EU^{FD}}{EU^{SD}} \right)}_{>0} + \underbrace{\frac{\gamma}{2} \left( \frac{(\partial EU^{FD}/\partial \gamma) EU^{SD} - (\partial EU^{SD}/\partial \gamma) EU^{FD}}{EU^{FD} EU^{SD}} \right)}_{<0} \quad (\text{D.1})$$

**Proof.** As shown in (D.1), the derivative of  $\phi(\mu; \gamma)$  with respect to  $\gamma$  can be written as the sum of two components, the first one being positive. Consider now the effect of the change in  $\gamma$  on the dealers' expected utilities' ratio. Computing this derivative yields  $\partial(EU^{FD}/EU^{SD})/\partial \gamma < 0$ , proving our claim.  $\square$

To fix ideas, it is useful to consider the unregulated monopoly case. At the optimum, the monopolist supplies

$$\mu^M = \frac{\phi - c}{-\phi'}.$$

Differentiating the above expression with respect to  $\gamma$  (and denoting  $\phi'$  by  $\partial \phi / \partial \mu$ ) yields

$$\frac{\partial \mu^M}{\partial \gamma} = \frac{1}{(\partial \phi / \partial \mu)^2} \left( -\frac{\partial \phi}{\partial \gamma} \frac{\partial \phi}{\partial \mu} + (\phi - c) \frac{\partial^2 \phi}{\partial \mu \partial \gamma} \right) \begin{cases} > 0 & \text{amplification} \\ < 0 & \text{attenuation} \end{cases}$$

If a permanent shock to  $\gamma$  shifts  $\phi$  upwards ( $\partial \phi / \partial \gamma > 0$ ) and makes it flatter ( $\partial^2 \phi / \partial \gamma \partial \mu < 0$ ) it leads the monopolist to increase its supply of technological services, inducing an

amplification of the initial shock. Conversely, a sufficient condition for attenuation is  $\partial\phi/\partial\gamma < 0$  and  $\partial^2\phi/\partial\gamma\partial\mu > 0$ .

We run simulations to gauge the effect of platform capacity decisions on liquidity, in the presence of a permanent reduction in dealers' risk aversion. For  $\gamma$  decreasing from  $\gamma^{orig}$  to  $\hat{\gamma} < \gamma^{orig}$ , we define the percentage of the direct positive effect on  $\Lambda_t$  mitigated by the indirect-platform competition effect as follows:

$$\%mit \equiv 1 - \frac{\text{Total Effect}}{\text{Direct Effect}} = 1 - \frac{\Lambda_t(\hat{\gamma}, \mu(\hat{\gamma})) - \Lambda_t(\gamma^{orig}, \mu(\gamma^{orig}))}{\Lambda_t(\hat{\gamma}, \mu(\gamma^{orig})) - \Lambda_t(\gamma^{orig}, \mu(\gamma^{orig}))},$$

where the Direct Effect at the denominator in the above expression captures the change in liquidity that obtains when only  $\gamma$  changes, and  $\mu$  is kept at the value it had prior to the the shock to risk-tolerance. Accordingly, if  $\%mit < 0$  ( $> 0$ ), the direct effect is enhanced (mitigated) by the indirect effect, and if  $\%mit > 1$ , the indirect effect *overturns* the direct effect. Figure D.1 displays the result of a simulation in which the mitigation effect can be strong enough to overturn the direct negative liquidity impact of a reduction of dealers' risk tolerance for  $\Lambda_2$ .

**Numerical Result 6.** *For second period liquidity, with standard risk aversion, a 10% decrease in  $\gamma$  leads to*

1. *Mitigation in the case of the unregulated monopolist.*
2. *Both mitigation and amplification are possible at the CFE when payoff volatility is low.*

A shock to  $\gamma$  does not lead to a parallel shift in  $\phi$  (see Figure D.1, Panel (a)). Thus, its ultimate effect on second period liquidity (amplification vs. attenuation) depends on the value of  $\mu^M$  or  $\mu^{CFE}$  pre-shock. For example, for a range of values close to the origin, to which  $\mu^M$  belongs, a 10% shock shifts  $\phi$  up, and flattens the inverse demand curve. These two effects are responsible for the observed attenuation at the monopoly solution which occurs at all  $f$ , since  $\mu^M$  is independent of  $f$  (see Figure D.1, Panel (b)).

For larger values of  $\mu$ , to which  $\mu^{CFE}$  belongs, the effect of the shock on liquidity is more complicated because the pre-shock value of  $\mu$  depends on (i)  $f$  and (ii)  $N$ . For the values of  $\mu^{CFE}$  that correspond to  $f \in \{1 \times 10^{-7}, 2 \times 10^{-7}\}$ , the shock shifts  $\phi$  mildly down ( $\partial\phi/\partial\gamma > 0$ ) and makes it steeper ( $\partial^2\phi/\partial\gamma\partial\mu < 0$ ). Each platform faces

a smaller mark-up and a steeper demand curve, and cuts down on  $\mu_i$ . This induces a profit increase that prompts entry. The paradoxical result is that we observe entry with a *reduction* in aggregate  $\mu$ , and thus amplification (see Figure D.1, Panels (c) and (d)). As  $f$  increases, both attenuation and amplification can obtain, because the pre-shock value of  $\mu$  shrinks, but stays in the region where the shock to  $\gamma$  has a complex effect on  $\phi$ . When parameter values are such that the industry supply increases and entry occurs (as in the cases  $f \in \{2 \times 10^{-6}, 2.1 \times 10^{-6}, 2.2 \times 10^{-6}\}$ , in Figure D.1, Panel (c)) attenuation is so strong that a reduction in  $\gamma$  leads to an increase in second period liquidity (see Figure D.1, Panel (d)).
